LIST OF CONTRIBUTORS TO VOLUME CXXIV.

Those whose names are marked with an asterisk have contributed editorial articles.

ABBE, ROBERT, M.D., New York.
ABT, I. A., M.D., Chicago.
ADAMI, J. GEORGE, C.B.E., M.D., F.R.S., Liverpool.
ALEXANDER, FRANZ, M.D., Berlin.
ALFORD, LELAND B., M.D., St. Louis, Mo.
ALPERT, N., M.D., Baltimore, Md.
ARMSTRONG, W. W., M.D., Baltimore, Md.
ASPINWALL, F. E., M.D., Miami, Fla.

BAINBRIDGE, WILLIAM SEAMAN, Sc.D., M.D., C.M., New York.
BALENSWEIG, IRVIN, B.S., M.D., New York.
*BANCROFT, FREDERIC W., M.D., F.A.C.S., New York, N. Y.
BARSKY, JOSEPH, M.D., New York.
BEHAN, RICHARD J., M.D., Pittsburgh, Pa.
BEINHAUER, L. G., M.D., Pittsburgh, Pa.
BEL, GEORGE S., M.D., New Orleans, La.
*BENJAMIN, HARRY, New York, N. Y.
BESSESEN, DANIEL H., M.D., Minneapolis, Minn.
BIRNIE, C. W., M.D., Sumter, S. C.
BLAU, ARTHUR I., M.D., New York.
*BLAUNER, SAMUEL A., M.D., New York.
*BOAS, ERNST P., M.D., New York
BOORSTEIN, SAMUEL W., M.D., F.A.C.S., New York.
BRADLEY, WILLIAM N., M.D., Philadelphia.
BRAGMAN, LOUIS J., M.D., Syracuse, N. Y.
BRISTOL, D. LEVERETT, M.D., Dr.P.H., New York.
BROOKE, CHARLES R., M.D., Newark, N. J.
*BROWN, MABEL WEBSTER, New York.
BROWN, SAMUEL A., M.D., New York.
BROWNNE, JOHN S., New York.
BUSSEY, DONALD G., M.D., Los Angeles.

CAMPBELL, MEREDITH F., M.D., New York.
CELCE, FREDERICK W., M.D., Philadelphia.
CLARK, L. PIERCE, M.D., New York.
CLOCK, RALPH OAKLEY, M.D., F.A.C.P., Pearl River, N. Y.
CLOUTING, CHARLES A., M.D., London.
COATES, VINCENT, M.A., M.D., M.R.C.P., Bath, England.
COHN, MARK, M.D., New York.
CRICHTON-MILLER, H., M.A., M.D., London.
CROFT, LEONARD E., M.D., Los Angeles.
CULVER, GEORGE D., M.D., San Francisco, Calif.
*CUMSTON, CHARLES GREENE, M.D., Geneva, Switzerland.
CUSHING, HARVEY W., M.D., Boston.

DE FRONZO, M., M.D., Newark, N. J.
DELAVAN, D. BRYSON, M.D., New York.
DENHAM, ELSA, New York.
DE RIVER, J. PAUL, M.D., San Francisco, Calif.
DE SCHWEINITZ, GEORGE E., M.D., Philadelphia.

The "John Bull" Spirit in Medicine*

H. CRICHTON-MILLER, M.A., M.D. (Edin. and Pavia)

London

The department of medicine in which I work is one in which racial characteristics assume considerable importance. The different qualities which a patient owes to his heredity go a long way to determine the prospects of cure by psychotherapy. It is true that a man can be a good patient or a bad patient and that this quality will show up more or less whether he be suffering from eczema or sarcoma. It is also true that a man's capacity to adjust to illness depends on many factors beside his heredity—his upbringing, for instance, his past experience, his age and so on. And this is true in psychotherapy as well as other branches of therapeutics. But in my department racial and hereditary factors are of special interest. In psychological work a prognosis must necessarily be influenced by them to no inconsiderable extent. For instance, hysteria tends to be much more curable in women of northern blood than in those of Latin origin. Obsessional and compulsion cases tend to be less tractable when the patient is of Celtic descent. Furthermore, some cases reveal important conflicts in respect of race consciousness. Some have a profound inferiority sense based on the knowledge that they are partly descended from races held to be inferior. Others have a mixed origin that brings with it temperamental incompatibilities. One of the most baffling cases I ever treated was a young man who was half French and half Semitic. Despite great intellectual ability and many social advantages his ill matched endowments produced unceasing conflict in his mind.

Dealing as I do, then, with personal problems that involve the race factor I have frequently pondered on our professional characteristics as conditioned by our national heritage, and it struck me that a study of this kind might be sufficiently interesting to justify my selection of it for this address. I was fortified in my choice by the reflection that I have studied at and graduated from a foreign university as well as from Edinburgh and have thus had opportunities that every one has not enjoyed of comparing men and methods of different races.

The characteristics of the British are traditionally labelled by the name of John Bull. The cartoonist all over the world represents the British public or the British government by the symbol of an early Victorian gentleman of considerable weight, obvious determination and menacing solemnity. From an anthropological point of view he is correct enough, a pure Anglo-Saxon. There is no trace of the Celt in his brachycephalic cranium, his nose gives no evidence of a semitic contribution, his skeleton is too large and clumsy to suggest any Latin infusion, and he is too short to pass as Scandinavian. If then we accept him physically as representing a racial type—perhaps a racial ideal—what about the psychological side of the picture? Well, in the first place John Bull's dress is unquestionably symbolic of traditionalism. As a race we certainly tend to be traditionalists. Precedent means more to us than to any other civilized race, excepting perhaps the Japanese. If you doubt this, I suggest that you seek the opinion of an unbiased foreigner on the Book of Common Prayer or the Imperial scale of weights and measures.

TRADITION

But tradition is not a bad thing in itself; it represents—or ought to represent—the accumulated experience of past generations. It becomes a bad thing, however, when men cease to apply to it respectful criticism and when they regard it either as an adequate justification for continuing on a prescribed course or as a final reason for destroying an institution. Whether the British are as completely fettered by tradition as some of our critics maintain, I do not propose to enquire. But it does interest us to ask how far tradition dominates our profession and whether we are more or less sensitive to change than the rest of our compatriots, and still more it interests us to compare ourselves with our colleagues of other lands.

In answer to the first question, I would venture to submit that the British doctor is by no means more bound by tradition than many another Britisher. It is true that in engineering and architecture, in journalism and education, advances are being made in the Empire at a very gratifying rate. But if we have not shown comparable advances we can at any rate comfort ourselves that we are less fettered by the past than the farmer, the lawyer and the parson.

It is the boast of many an elderly doctor that he is prescribing the identical mixture for psoriasis that he was taught as a student thirty years ago. This is

*Annual address to the Sunderland Division of the British Medical Association, delivered November 12, 1925.

624317

deplorable, not only because the fact should be an occasion for modest reticence, but also because it indicates that he has been content to prescribe for all these years a remedy which did no appreciable good. The doctor who is less content with the experience of his teachers may have no greater success in the treatment of this particular affliction, but he will at least have tried out a number of equally ineffective novelties. You will say that the result, as far as the patients are concerned, is the same. True, but there is a difference. The first man complacently moving along the groove of the past could never discover a better method; the second, with all his fruitless experiments might have stumbled on a real improvement. Then do I suggest that a doctor should try every new nostrum and believe every advertisement that he receives? Far from it—but I do affirm that a reasonably critical attitude towards tradition would prevent any man from continuing to prescribe an ineffective remedy and would drive him to an empiricism that could not be less valuable and might result in positive gain. On the other hand experimentalism in new remedies is unquestionably a growing evil, abroad if not at home. Commercial exploiters of new preparations are tempted to condemn older remedies unfairly. Their propaganda tends to make the physician lose his respect for a traditional form of treatment and to adopt the new simply because it is new, and not because he has found it to be better. Taken all round I submit that the English doctor cannot be acquitted of a certain sterilizing satisfaction with oldfashioned methods. On the other hand he does hold on to a good thing when he gets it and that is more than can be said of the average doctor in some other lands.

DETERMINATION

But to return to John Bull's psychological characteristics. I have said that he gives the impression of obvious determination. Here I think we may claim a fairly high place. Determination, in so far as it may be assessed as a racial characteristic, belongs to the men of the mountains and to the seafaring races preeminently; in so far as it belongs to any particular profession, it is naturally to be found in those professions which cannot be entered without it. In any land doctors must be among the most determined spirits, for in general there is no more exacting nor arduous training than that which our profession demands. And it is well it should be so, else what sort of a fight would we put up against asthma and otosclerosis and against tabes and varicose ulcers? Yes, determination is a quality that means much to a doctor and we may well be thankful that our racial endowment has been fairly generous in this respect. But we live in an age that accentuates achievement and discounts endeavor. On all sides short cuts are being devised and effortless solutions propounded. Quick wits are valued higher than stout hearts. The telling advertisement of the charlatan or the convincing selfpraise of the qualified quack make a stronger appeal than the steady, unostentatious but thoughtful pertinacity of the good practitioner.

We may console ourselves with the knowledge that we are not alone in this situation. The manufacturer, the builder, the publisher, the educationist, all will tell you the same tale. The public of today is increasingly superficial in its judgments. It looks for immediate returns and surface values. It is too impatient to assess durability and too shallow to investigate hidden worth. This is one of the reasons why good doctoring is not appreciated today as we might expect it to be. For good doctoring is thorough doctoring, and a thorough doctor is a man with determination. But this failure on the part of the public is, I believe, a transient phase. It comes from a shallow materialism that belongs to the halfeducated classes. As the educated classes become more truly educated there will be a reaction, I venture to hope, in favor of thorough work and durable goods. When that change comes I hope and believe that our nation in general and our profession in particular will come into their own. For, say what you like, we are on the whole a thorough race. Our thoroughness makes us slow and our American cousins get there before us. It makes us and our goods dear and the continental undersells us. Nevertheless I hope we may never sell our birthright of thoroughness for any mess of pottage, commercial or professional. We are, I think, notably free from that spirit of "make do" that characterizes some other races. I have contemplated an Italian medical student dressing a wound and a French cavalryman grooming his horse; I have investigated a German mechanical toy and the carburettor of an American car and in each case I have been able to reflect, I think with justice, that in Britain we do these things more thoroughly.

SOLEMNITY

So much then for John Bull's determination. I have said that he wears an expression of menacing solemnity. Are we to admit that this is deserved? If it be in truth a racial characteristic it is unfortunate for us doctors for a solemn doctor is generally a pedant and that is nearly as inappropriate as being frivolous. True, we lack profoundly the animation of the Latin races and the emotional range of the Celts, but we can at least hold on to the fact that we are not as stolid as the Teutons. Let us leave it at that, lest we find ourselves involved in the fruitless discussion as to whether a Scotchman can see a joke.

COMMON SENSE

But let us go a little further than the cartoonists' symbol can take us. What further characteristics can we boast of, or must we confess to, and what has been their influence on our profession? I think the first is common sense. This is a quality that some other races take little notice of. Indeed there are languages in which the idea can only be expressed by a periphrasis. The Englishman has always prided himself on common sense. He has made it (in the form of a jury) into a legal force. He has continually pitted common sense against technical and expert opinion, sometimes if not often with disastrous results. Common sense is the quality which depresses reformers and would be reformers in this country. Whether it be a fruitarian diet or an E. R. A. cult, an esoteric cure for tuberculosis or a social revolution, it is common sense backed by traditionalism that seems to save us. But it is clearly possible to be misled by an undue dependence on common sense, and it must, I think, be admitted that our national worship

of common sense is the cause of our frequent failure to give adequate weight to expert opinion. For instance, I venture to say that in no country has education been so predominantly controlled by laymen as in our own. Educational experts are now coming into their own, much as is the case in other lands, but hitherto we have applied the common sense principle and trusted to those without expert knowledge to direct a great part of our educational activities.

In medical matters it is our common sense that makes us sceptical of new methods especially if these be based on farfetched theories. I recall in this connection a new cure for tuberculosis which its foreign discoverer tried to launch in this country. It consisted of injections of immunized crocodile serum. The theory on which it was based was that only amphibians had blood platelets of the same shape as ours and that therefore only their serum could convey acquired immunity to the human subject. As far as my knowledge goes, this benefactor of the human race gave up very speedily the unequal contest with British common sense and beat a retreat to somewhere nearer home. On the other hand there are historical examples of real reforms that have been resisted in the name of common sense. Lister's antiseptic methods were, as you may read in his biography, known and practised on the continent when in this country he had hardly a following. They did not appeal to the common sense of British surgeons of the day. Indeed the whole of our professional work must necessarily involve a balancing of two points of view—on the one hand the particular and theoretical, and on the other hand the general and practical. Plato claimed that "a sense for the whole is the sign of the sound mind." Sometimes we trust that "sense for the whole" too much, and at other times not enough. But in general it may be said that if we tend to rely too much on our common sense, it is usually safer for our patients than if we lost sight of the whole in exaggerated enthusiasm over a single hypothesis.

SPIRIT OF FAIR PLAY

There is another and important attribute which impartial observers usually attribute to our race. It is the spirit of fair play. In all his work a doctor tends to be in a position of advantage. We sometimes forget this. We think of ourselves as being at the mercy of inconsiderate patients who call us out of our beds on inadequate grounds, or of capricious patients who discard us when they imagine that some one else can cure them more quickly. But in point of fact it is we who generally hold the trump cards and it is the spirit of fair play that prevents us from making use of them. In the first place any doctor can frighten a patient and in the second place any doctor can bewilder a patient. If we are sufficiently cowardly and sufficiently unscrupulous, how easy it is for us to impress the patient unduly with the severity of his complaint and how easy to talk in technical terms, incomprehensible to him, of the baffling nature of that complaint. Once upon a time I practised in a foreign health resort. A native practitioner who combined broken English with perfect foreign manners had a large clientèle of English and American visitors. His methods were extraordinarily simple. The first time he saw the patient he told her—they were mostly women—that she was suffering from bloodlessness, that her symptoms were all due to "cerebral anemia" and that he could cure that by a course of injections. The course would last six weeks and he would give two injections a day. Yes, it was a great pity that English doctors didn't know about these injections. Having duly administered with his own hand two injections of iron and arsenic for forty days, he explained that the patient was no longer anemic, that he had just caught the disease in time and that now the patient's nerves needed electrical treatment. For this he proposed a six weeks' course of electricity which came from a small coil that he carried about in his bag. At suitable intervals the patient was made to realize how serious the consequences were of allowing the nerve cells to deteriorate for lack of skilled treatment. In all this one felt a natural revulsion from the unscrupulous trading upon the patient's ignorance and credulity, notably the latter. I suppose there are doctors in our country that would stoop to such methods but on the whole I think our sense of fair play keeps us from exploiting our patients and that whatever other shortcomings we have we can honestly claim that our patients get as square a deal as patients in any other country—and perhaps a little more. Commercial exploitation is not, however, the only form that exploitation takes. In some countries the spirit of clinical research is stronger than it is with us. When I cast my eye over the literature that accompanies some new chemical preparation from Germany, with its glowing account of extensive clinical trials, I am prone to wonder how many patients are unwittingly sacrificed on the altar of pharmacological research. And on the whole one is glad that the medical men of other countries are so zealous in trying out new remedies, so that we may offer to our patients new drugs of which something at any rate is already known.

But it is not only in practice that the spirit of fair play counts for so much. In the matter of examinations and the granting of degrees much depends on even-handed justice. The public needs protection, and where there is any taint of corruption in examining bodies it is obvious that ill qualified doctors must be let loose on the helpless community. In this connection I recall an incident at an Italian university that is worth recording. If we are to believe all we hear of Mussolini's purgative power, we may surmise that such an incident belongs to past history. Clinical examinations are, or were, conducted in public. I was present at the examination in clinical medicine for the degree examination. There were two examiners; one was the principal of the university, a man whose name would be familiar to every one of you; the other was a professor well known in his country. A candidate was summoned and sent to examine a case of acute lobar pneumonia about the seventh day. A friend of mine whispered to me "Listen carefully; this man knows nothing, but you will see that he passes for he is protected." This meant that some influential friend had "recommended" the candidate to one of the examiners. The professor took him in hand, while the principal studiously read a newspaper. This was an imperative act of courtesy. If he had listened, or appeared to listen, to the questioning, it would have suggested

that he doubted his colleague's complete impartiality. The candidate, having completed his examination, began his crossexamination rather unfortunately. In fact he placed the pneumonia on the wrong side. However that was passed over. A few very general questions on pneumonia failed to reveal any very intimate acquaintance with the disease. At last the professor said, "Pneumonia is a selflimited fever, is it not?" "Yes, sir." "And it lasts seven . . ." "weeks," added the candidate, with an air of one who has at last touched bottom. A fortnight later he was a qualified doctor.

There is yet another aspect of this spirit of fair play that I think is worth touching on. I suppose you and I have all felt pretty often a sense of acute exasperation at the misplaced sentiment, exaggerated humanitarianism and special pleading of the antivivisectionists. They deserve little of the community. Nevertheless it behoves us to remember that our very stringent Home Office regulations might well be copied in other countries. I once went into the sideroom of a surgical ward in a large foreign hospital. I found my friend the house surgeon, assisted by a clerk, dissecting out the thymus in a puppy. I asked if they had given it any anesthetic but they explained that if they had it might have died. You probably feel that such an incident could not have happened in this country whether we had regulations on the subject or not. Be that is it may, I think we can all agree that fair play to patients, to candidates and even to puppies, is solid ground for modest gratification.

MODESTY

And now I turn to a very different characteristic of our race. I have just used the adjective modest. Sexually we claim to be modest and modesty is, by the critic, generally pronounced prudery. How far we are modest and how far we are prudish I do not propose to discuss. My psychoanalytical friends will explain to you, if you care to ask them, how all modesty *is* prudery. Be that as it may, this racial characteristic affects medical practice in ways that are so obvious that I need not stop to point them out. I would like, however, to draw your attention to one aspect of it.

There is no other civilized race in which lay opinion is so wilfully ignorant of elementary anatomy and physiology. Let me give two little incidents as a contrast. Some time ago a bishop's wife told a woman friend that she was in great distress because her sister had just had "a dreadful internal operation," adding "Of course I don't understand what it was but—you know—something to do with her inside." In point of fact the operation was an oöphorectomy. Shortly after this we were staying in France. One morning Yvonne, our pleasant chambermaid, appeared with very red eyes. My wife asked her if anything was wrong and at once she answered, *"C'est que ma soeur vient d'être operée pour une salpingite."* She knew all about salpingitis. For her there was no vague "internal operation." Medical men in this country take for granted a complete ignorance on the part of their patients. They do not realize how much better informed most foreigners are in matters of health and disease. Hence as a profession we are enabled or encouraged to assume an air of professional aloofness which patients of other races would not tolerate for a moment. I have frequently heard complaints on this score from foreigners and from English patients accustomed to foreign doctors. They say that the English physician resents their asking for any explanations, as if it were an equivalent to an aspersion on his competence. I believe that the best doctors realize that ultimately it is the soundest policy to spend time and exercise patience in helping both invalids and relatives to understand a little what is wrong with them and what the immediate aim of treatment is. In fact I rather think that we need to "come off the perch" of medical sacerdotalism.

OBJECTIVITY

And now I come to the last and perhaps the most unfailing of John Bull's attributes. He is incorrigibly objective. Anything that he can see and feel counts with him. I venture to say that the intangible, the speculative, the metaphysical, make less appeal to us than to any other race. John Bull has prided himself for generations on the number of things that he could not be bothered with because he considered them damned nonsense. For generations he has congratulated himself on being "downright;" on being a "plain Englishman"—in fact, on being everything but subtle. We are indeed the least subtle of races. As the European is to the Oriental, so is the Englishman to the continental. Life for the Anglo-Saxon is an affair of black and white. Where others put in shading we impatiently demand extremes.

Now this objective spirit runs through our whole national life and in the sphere of therapeutics it is constantly operative. Consider a few examples. Take an eczematous child. The obvious thing to do is to apply an ointment. When that has failed and perhaps many others the diet may be regulated. When the case is becoming chronic we murmur something about "constitutional." But if you ask Dr. John Bull whether he has inquired into a famliy history of asthma, he thinks you are clearly paraphrenic. Yet some profound hereditary flaw exists, probably in the endocrine system, which conditions asthma in a mother and eczema in her child. Can you get a selfrespecting Anglo-Saxon physician to interest himself in a theory so fantastic? I trow not.

Again take varicose veins and ulcers. Local applications, support, even excision—all these are objective and downright methods. But parathyroid treatment, based on an abstruse theory of the calcium content of the blood—this is sheer speculation—let us try another elastic stocking!

Again consider epilepsy and petit mal. We understand very little of the etiology of these conditions, yet in the war we saw enough of these conditions to realize that between epilepsy of the socalled idiopathic variety and hysteroepilepsy there is no sharp line of cleavage. Let me give you an example. A young woman of seventeen, in every other way healthy and well developed, suffered from petit mal. She had been treated by several of the best known neurologists of the land. Some had advised bromides, some had prescribed luminal. All had agreed that "her brain must have a rest," consequently her education had been completely suspended and she had been treated as a partial invalid. When she

came under treatment she was having an average of eight attacks a day. Now she has much less than that in a week, despite the complete suspension of sedatives. Treatment was begun in no very sanguine spirit for there was nothing obvious to suggest the presence of serious conflicts and repressions but gradually there began to emerge a picture of considerable interest. First we saw a rather complex emotional attitude to the parents and a definite resistance to growing-up. Then by hypnoanalysis a number of completely forgotten emotional experiences were recalled. Then from her dreams she discovered how the petit mal had been used and maintained as a defense against facing the dangerous and the uncongenial in life. Finally a sex perversion of considerable importance was brought to light. The result is that now no attack occurs which the patient is not able to refer to a specific emotional conflict. But there is a further point of great interest. Whereas the patient had never suffered from grand mal, she has during the latter stages of treatment had five major attacks and each one of these attributed by herself to an acute emotional conflict. I believe this patient will be completely cured.

Do not imagine that I am contending that all epilepsy is due to emotional causes, still less that I am propounding a theory of the disease. I know just as little as you do of the real nature of the cortical instability which manifests itself in epilepsy. But I have recorded this case as an illustration of the failure of the objective physician. A fit associated with high blood pressure or with acidosis is a thing he can get hold of—he sees an alternative to mere symptomatic therapy in the possibility of treating a definite physiological defect. Treatment of a "cause" that gives definite mercurial readings or chemical reactions appeals to the man of objective mind. But it is fortunate for mankind (if embarrassing to the John Bull mind) that man is more than a bundle of physiological reactions, and therefore a patient is not merely a case but also a personality.

Hence, the physician, who would accept his full commission, must take into his purview factors of thought and feeling, of instinct and emotion, of training and temperament. He must realize the numberless subtle points at which emotional experience can produce physical reactions. He must face the fact that cortical localization is no final conception in medicine and that even biochemistry is subtly involved in the processes of thinking and feeling.

Our racial objectivity endows us with a strong resistance to such vague and undemonstrable views. We feel that when we have gone as far as laboratory investigation will take us we have gone as far as any selfrespecting practitioner is required to go. And so it comes about that in countries where speculative thought is less scorned, advances are being made beyond anything that we can show in this country, in a therapy that takes into account the subjective experiences of a patient in a way that is eminently called for. If you doubt me, I ask each of you to think of the last patient who consulted you about a phobia or an obsession. Perhaps he was a healthy man in middle life, whose family you had looked after for years. Perhaps he began with an embarrassed and shamefaced confession that he seemed to be "getting very queer and that he didn't like it but the fact was he couldn't stand being left in a room alone, and that when he was he would either slip out or creep to the door and open it stealthily." Now recall what you said and did to that patient. You began by feeling his pulse and inspecting his tongue and carefully auscultating his heart. During this examination you felt that you were grimly holding on to the realities of life and disease but you were probably haunted by the uncomfortable feeling that you had never yet detected an aortic murmur in a patient who complained only of a phobia. Then you proceeded to tell him that he was as sound as a bell and that it was merely a matter of "nerves" for which you proceeded to prescribe what you told him was a nerve tonic. Now I ask you what you meant by the word nerves in this context? Not I presume the central nervous system, still less the peripheral. You used a word with an objective denotation for a subjective connotation. May I suggest that you were using a popular phrase to describe something you didn't understand, that you were in fact trying to persuade yourself that this intangible syndrome with its mysterious etiology really had a concrete and structural basis of a neurological character? And, having committed yourself to this illuminating diagnosis of nerves am I not right in surmizing that you proceeded to combat the disease with the following remedies: bromides, ridicule, valerian, golf, a pluriglandular extract of brain substance, and a sea voyage? Perhaps it would be cynical to suggest that when you offered the last named remedy you secretly hoped that the patient would not return from it.

Now I venture to submit that this is a perfectly legitimate picture of the therapeutic morass in which we find ourselves when we endeavor to reduce to objective categories, symptoms that are essentially subjective. I do not contend, please note, that the etiology of a phobia must be exclusively psychic, but I do strongly hold, and beg you to remember, that we cannot begin to treat such conditions successfully until we have schooled our objective Anglo-Saxon minds to contemplate an etiology that is not exclusively objective. You may possibly throw back at me some of my own views expressed in an earlier part of this paper, suggesting that I am now asking you to plunge into empiricism and metaphysics. I reply on the other hand that there is nothing so unworthy of our medical tradition as to prescribe remedies for which we can give no rational justification and to which we can attribute no therapeutic efficacy. And I maintain that the people who get the best results in such a case as I have described are those who unite an insight into the complexities of personalities with a knowledge of the human machine and its workings.

CONCLUSION

And so we see that to the John Bull spirit we of our profession owe much, or ought at least so to do. Yet we must acknowledge that it implies certain tendencies, notably to rigidity on the one hand and to a lack of vision on the other. I see no reason why we should not improve ourselves in these ways, provided that we recognize them as limitations instead of complacently glorying in our shortcomings.

146 Harley Street W 1.

Acute Pericarditis

HERMAN ELWYN, M.D.

New York

The seeming increase in rheumatic cardiac disease in recent years demands on the part of the physician a better understanding of those manifestations which indicate the degree of severity with which the heart is affected. Such a manifestation is the appearance of acute pericarditis in the course of rheumatic fever or of rheumatic cardiac affection. Acute pericarditis occurs also in the course of other diseases and although it is always secondary to such a disease yet it may at times constitute the only or the earliest manifestation. The physician who wants to evaluate properly the significance of an acute pericarditis must be familiar with its clinical manifestations, its progress and course, and with the diseases in the course of which it commonly occurs.

FUNCTIONAL CONSIDERATIONS

The presence of an inflammatory exudate in the pericardium modifies the function of the heart in a twofold manner. First, the inflammation is not strictly limited to the epicardial layer but involves also the ventricle itself to a variable depth. The contractility of the involved muscular fibres is necessarily impaired. The extent of such impairment is dependent upon the original disease, upon the virulence of the infecting organism, and upon the inflammatory reaction in the layers of the ventricle.

Secondly, the function of the heart is influenced mechanically by the amount of the exudate. When this is purely fibrinous, the amount is usually not sufficient to cause any mechanical embarrassment of the heart. When the exudate is liquid, such embarrassment is dependent upon two factors, the amount of the exudate, and the slowness or rapidity with which it accumulates. This problem has been carefully studied by Cohnheim (1), and his results corroborated by Starling (2), and others.

Normally, the pericardial sac is practically an inelastic membrane and one of its functions is to prevent the overdistention of the heart. When fluid is suddenly injected into the pericardium the sac is put under tension and holds only a limited quantity, from 150 to 200 c. c. Greater quantities may be injected under pressure and this is followed by an alteration in the structure of the parietal layer. When the pericardium is inflamed, and when fluid accumulates gradually in the sac, the parietal layer becomes thin, atrophied, and stretched sufficiently to allow the accumulation of fluid up to two litres and more. The mechanical effect of the fluid differs, therefore, whether it accumulates slowly or is suddenly thrown in the pericardium.

An example of sudden accumulation of fluid is found in the case of rupture of the heart with resulting hemopericardium. Here the presence of 150 to 200 c. c. of blood in the pericardium is sufficient to cause death. The manner in which death occurs in such a sudden accumulation of fluid has been settled by the experiments of Cohnheim. He found that the injection of a certain amount of oil in the intact pericardium is followed by a fall in the arterial and a rise in the venous pressure. Starling found that, following the injection of 70 c. c. of oil into the pericardial sac, the arterial pressure fell and the pressure in the portal vein and in the inferior vena cava rose. The ventricular output is diminished until no more blood is expelled by the ventricles. According to Cohnheim the ventricles still continued to beat for some period, which is shown by the pulsation of the oil manometer, but as no blood is expelled the contractions soon cease.

There have been various explanations for the behavior of the heart under these circumstances. Some observers have held that the presence of the fluid in the pericardium prevents the ventricles from expanding sufficiently in diastole. Others have assumed a reflex effect of the depressor nerve on the vasomotor centre. The inferences which Cohnheim has drawn from his experiments rightly explain the manner in which the heart behaves following the sudden filling of the pericardium with fluid. According to Cohnheim, the sudden filling puts the inelastic sac on the stretch. This causes a compression of mouths of the venæ cavæ, and also prevents the more easily compressible auricles from expanding properly in diastole. The result is a diminished inflow into the auricles, a diminished ventricular output, and increase in venous pressure. As the latter increases it overcomes at first the hindrance to the inflow into the auricles. But as the pericardium is put more and more on the stretch, the venous pressure is unable to overcome the hindrance, blood does not enter the auricles, and the heart pumps itself dry and soon ceases to contract.

When the fluid in the pericardium accumulates slowly, as occurs in the case of most inflammatory exudates, the pericardium becomes adapted to its contents by stretching and thinning. Under these circumstances it may contain a considerable amount of fluid without markedly interfering with the inflow of the blood into the auricles and without much lessening of the ventricular output. When the amount of fluids becomes sufficiently large, the eventual effect on the heart is similar to that of a sudden filling. The tension on the venæ cavæ and the pressure on the auricles result in a diminished auricular filling and a diminished ventricular output.

Of some importance is the knowledge as to where the fluid first accumulates in the pericardium. The older clinicians, such as Skoda and Bamberger, had already recognized the fact that the fluid accumulates early at the base of the heart, in the socalled recess of the pericardium in the region of the great vessels. Experimental investigations (Williamson, 3) have shown that a small amount of fluid first accumulates on the surface of the diaphragm at the margin of the heart. When the quantity is larger, it fills the pericardial recess at the base of the heart. According to Curschmann (4) the heart is pressed anteriorly and, when the quantity is large, is in contact with the chest wall. On opening the pericardium, the heart sinks posteriorly with the outflow of the fluid.

When the fluid in the pericardium is sufficiently large it exerts pressure on the neighboring organs. As the fluid accumulates at the base of the heart, especially at the left side, the upper lobe of the left lung retracts. With the increase in amount of fluid there is a retraction and later a compression of a part of the left lower lobe posteriorly. These retractions produce physical signs which are of diagnostic value. Compression of the mediastinal structures such as the esophagus or the trachea is extremely rare, occurring only with extremely large effusions.

CLINICAL FORMS OF ACUTE PERICARDITIS

Acute pericarditis occurs occasionally in the course of many of the infectious diseases, in leucemia, scurvy, and purpura hemorrhagica. It occurs occasionally in the course of the various forms of sepsis due to the streptococcus, the staphylococcus, the pneumococcus, or the gonococcus. It occurs by extension from a neighboring local infection, such as a mediastinal abscess, empyema, or abscess of the liver which perforates into the pericardium. In all these affections acute pericarditis is of rare occurrence. Clinically it is entirely overshadowed by the original disease and in some it is a precursor of death. In certain other diseases, acute pericarditis occurs much more frequently and is of much greater clinical importance. To the clinician an acute pericarditis first calls to mind the possible presence of acute rheumatic fever, of tuberculosis, of pneumonia, of myocardial infarction, of the possible presence of a tumor. The clinical forms of acute pericarditis include therefore: Pericarditis in the course of rheumatic heart disease, tuberculous pericarditis, as a complication of pneumonia, in uremia, in myocardial infarction, in tumor of the pericardium, and rarer forms.

PERICARDITIS IN THE COURSE OF RHEUMATIC HEART DISEASE

Acute rheumatic fever is by far the most frequent cause of acute pericarditis. The frequency with which it occurs varies considerably with the individual organs. Among the older clinicians, Latham (5) found in 136 cases of acute rheumatism the heart involved in ninety, the pericardium in nine, the pericardium and the endocardium in eleven. Bamberger (6) found pericarditis in fourteen per cent. of cases. Sibson (7) found twenty per cent. in 326 cases of acute rheumatism, Sansom (8), thirty-five per cent., Schrötter (9), thirty per cent., Rolly (10) found three per cent. in 911 cases of rheumatic fever; according to Jochman (11) it occurs in ten to twenty per cent. of the cases in children. Coombs (12) (p. 199) found evidence of acute pericarditis only in forty-four of 346 cases, or thirteen per cent., "yet postmortem evidence shows that the pericardium is or has been inflamed in over fifty per cent. of all cases."

More illuminating are the figures given by Coombs from the Bristol General Hospital as regards patients dying of rheumatic heart disease (p. 69): "In patients dying in the first decade 100 per cent. showed pericardial lesions; in the second, 83.3 per cent.; in the third, 41.6 per cent.; in the fourth, 23.0 per cent.; after the age of forty, 26.0 per cent.; and taking all ages together, 53.0 per cent."

The character of the pericardial exudate in rheumatic heart disease is fibrinous, serous, or serofibrinous, frequently also hemorrhagic. The latter is often due to rupture of small newly formed vessels in the vascular granulation tissue. In cases where paracentesis of the pericardium has been performed, the rupture of a small bloodvessel by the needle is responsible for the admixture of blood. The serous exudate is yellow to greenish, clear to cloudy. The quantity varies from one hundred to four hundred c. c.; larger quantities are not common, but occur occasionally.

Of great importance in showing the connection between rheumatic pericarditis and rheumatic infection of the heart has been the recent finding of specific rheumatic nodules or Aschoff bodies in the subendothelial layer of the epicardium. The nodules consist of large cells with one or more vesicular nuclei clustered together in a fibrinous matrix, accompanied by mononuclear cells and leucocytes. They have been found in the epicardium by Coombs, by Mönckeberg (13), and by MacCallum (14).

CLINICAL FEATURES

The connection between pericarditis and rheumatic fever has been known since the time of Pitcairn. Its recognition had been difficult previous to the discovery of the friction sound. Latham, in his lectures on diseases of the heart (p. 83), says that the older clinicians "when in the midst of acute rheumatism, there arose a precordial pain, an anguish of respiration, and an irregular action of the heart, they interpreted them to denote pericarditis, and they were generally right."

At the present time we have learned to watch constantly the cases of acute rheumatic fever for the appearance of signs of pericarditis. It may appear at any time in the course of the disease, even before the appearance of the joint symptoms and after their disappearance. We may expect the presence of an acute pericarditis in the course of acute rheumatic fever even before the appearance of the physical signs by the rise in temperature, the pain, and the general appearance of the patient. Although by themselves not characteristic, yet their collective presence calls at once for a thorough examination for the presence of a friction sound or of the characteristic increase in cardiac dullness. It must be fully realized, however, that acute pericarditis may be entirely latent without any subjective manifestation and without any rise in temperature. But when in the course of rheumatic fever or of rheumatic cardiac disease, there occurs a sudden or gradual rise in temperature to 102° or 103°, one should immediately suspect the presence of an active rheumatic infection of the heart, and that it may have spread to the pericardium.

Pain in acute pericarditis is an extremely variable symptom; it is most commonly referred to the sternum or the precordia, occasionally to the epigastrium, between the shoulder blades, or to the muscles of the throat and neck. The pain is usually localized and moderate in degree, but there are cases in which it becomes very severe with the intensity, character, and radiation of a typical attack of angina pectoris.

The general appearance is in some manner characteristic. The patient is pale, with a distinctive milky white appearance of the face. The pallor is not commensurate with the degree of anemia which is usually present and is probably dependent upon the contrac-

tion of the superficial vessels of the skin. The milky white appearance of the face accompanied by a slight degree of cyanosis of the lips and some degree of dyspnea which causes the patient, usually a child or young person, to prefer the half sitting position, gives a distinctive general appearance. I have repeatedly seen one of my clinical teachers make the correct diagnosis of acute pericarditis on the general appearance alone. This, with the rise in temperature and the pain, causes the experienced clinician strongly to suspect that the rheumatic affection of the heart has spread to the pericardium.

Other symptoms are occasionally present. In one case, that of a young man of twenty years, with a mild attack of acute rheumatic fever, the sudden appearance of hiccough and of pain in the left shoulder accompanied by a rise in temperature aroused the suspicion of the presence of an acute pericarditis contiguous to the diaphragm. Twelve hours later the appearance of a pericardial friction sound confirmed the diagnosis.

Difficulty in swallowing has been described by many, and the cases of Sibson are usually cited by most writers. I have not seen a case in which difficulty in swallowing was a distinct symptom, but I remember the case of a young girl of fourteen years with a large pericardial effusion in which the pain in the sternal region was aggravated by swallowing. Dyspnea is marked when the effusion is large, but it is also frequently present when the exudate is mainly fibrinous. When the latter is the case the dyspnea is probably dependent upon the myocardial involvement. In fact, in all these symptoms, the pain, the dyspnea, and the fever, it is not always easy to separate the pericardial from the myocardial factor. It is for this reason that the recognition of the pericarditis is important, as it indicates the severity of the myocardial affection. In the last analysis this recognition is dependent upon hearing the friction sound and upon the changes on percussion.

The friction sound in acute pericarditis has been considered as diagnostic of this disease since the time of Collin. When typical and marked the sound has a rasping or scratching quality sometimes resembling the creaking of leather. It seems to be close to the ear, is not propagated beyond the borders of the heart, and is heard throughout both systole and diastole, being broken up in an irregular manner so that it is not synchronous with either systole or diastole. The pericardial friction sound is, however, not always typical. It varies a good deal in loudness, being at times very soft, and only audible after the patient changes his position either lying down or sitting up.

There are a few important factors to be kept in mind in connection with this friction sound. It can be heard at times even when a considerable amount of fluid is present in the pericardial sac, and it can be heard through a thick layer of either serous or fibrinous exudate. It may be entirely absent even in the presence of a fibrinous exudate. Its appearance is often preceded by a reduplication of the second sound, and at times it closely synchronizes either with systole or diastole or with both. Thus on two occasions the appearance of a diastolic murmur over the aortic area led to the diagnosis of acute rheumatic endocarditis involving the aortic valve. On both occasions this was followed a few days later by a more typical friction sound, and when the acute pericarditis had subsided there was no evidence of involvement of the aortic valve. Another important point is the appearance and disappearance of the friction sound within a few hours or from day to day. Latham in his lectures on the heart calls attention to this point. When the friction sound has a rasping or creaking quality it can often be felt as a thrill by the hand laid over the region of the heart. A pleuropericardial friction sound which is produced in the pleura overlying the border of the heart must not be confused with a true pericardial sound.

When the pericardial friction sound is heard the diagnosis of acute pericarditis is certain. Whether or not there is an accumulation of fluid in the pericardium must be determined by percussion. Here the knowledge of where the fluid accumulates is of value. From the experiments of Williamson, previously mentioned, we know that the fluid first accumulates over the diaphragm at the lower margin of the heart where we are unable to recognize its presence by physical signs. The next place where the fluid accumulates is at the base of the heart and here we are able to determine its presence by percussion. The extension of cardiac dullness upward into the second left interspace is the earliest physical sign of the presence of fluid in the pericardium. As the fluid increases in amount the dullness changes to flatness in this area and extends further to the left and also to the upper part of the sternum. The presence of such an area of increasing dullness or flatness with the presence of a friction sound unquestionably signifies an acute pericarditis with effusion. This percussion sign is of greatest diagnostic value, and even its presence alone should make one suspicious of pericardial effusion. The dullness or flatness in the second and the first left interspaces is due to the fluid in the pericardium taking the place of that part of the lung which is pushed aside. Stokes (15) cites a case (p. 57) with pleuritis and pericardial effusion "in which the singular phenomena occurred of the thrusting upwards of the lung so as to form a very large tumor above the clavicle."

Further evidence of the presence of a pericardial effusion obtainable by percussion is the existence of an area of dullness over the lower lobe of the left lung posteriorly. This area of dullness varies with the amount of effusion. It is never really flat, and vesicular breathing is usually heard over this area although slightly or considerably diminished. Only rarely is it replaced by distant bronchial breathing. This area of dullness is probably always present when there is a considerable amount of fluid in the pericardium. The explanation for its presence is to be found in the partial compression of the left lower lobe by the pericardial effusion. This sign was already noticed by Stokes, but he ascribed it to an accompanying inflammation of the lung. Other writers who speak of a rheumatic pneumonia have probably confused the presence of a compressed left lower lobe with true pneumonia. A recent writer has attempted to explain the presence of this sign by assuming a massive collapse of the left lower lobe. In a true massive collapse, however, the breath sounds are entirely absent, and not only diminished as in this sign. It is important to recognize that this area of dullness is due to the pericardial effusion, as its resemblance to the

signs of effusion in the pleural cavity has led to the useless tapping of this cavity.

With the increase in the amount of the pericardial effusion the dullness and flatness extends further down on the left side, and also to the right of the sternum. The apex beat frequently disappears. When the latter is still palpable the presence of the area of dullness or flatness outside of the apex beat is of diagnostic value. Leube considers it as the one sign of effusion in the pericardium. Of diagnostic value is also the change of the entire cardiac dullness to a wooden flatness.

With the increase in the amount of fluid the heart sounds and the friction sound frequently disappear, to reappear when the fluid becomes absorbed. But again one must keep in mind that the heart sounds as well as the friction sound may be heard throughout the entire course of the disease, even with a large amount of fluid.

An area of dullness obliterating or changing the cardiohepatic angle has been described by some writers. In my experience this is seldom present unless the amount of fluid is large. It is certainly not an early sign.

The character and frequency of the pulse are dependent a good deal upon the myocardial involvement. When fluid is present the frequency of the pulse varies from 100 to 160. The blood pressure is reduced, the pulse is small, sometimes collapsing, and in some cases cannot be felt during inspiration—the pulsus paradoxus. The jugular veins are distended and a positive venous pulse is occasionally observed.

Röntgen examination is, of course, of great value in the diagnosis of pericarditis with effusion. In the main the changes in the cardiac shadow correspond to the findings of percussion. For details the reader must look through the special works on the röntgen examination of the heart.

TUBERCULOUS PERICARDITIS

The occurrence of this form is much less frequent than that of rheumatic pericarditis. The frequency cannot be properly estimated from statistical tables inasmuch as many pathologists assume that cases of adherent pericardium which do not show any evidence of tuberculosis may well be the end result of a previous tuberculous pericarditis. Among the statistical tables available are those of Norris (16) who found eighty-two cases of tuberculous pericarditis among 7,219 general autopsies, 1,780 of which were autopsies on clinically tuberculous individuals. Norris also records three cases of tuberculosis of the pericardium among 387 autopsies at the Phipps Institute. Willigk, cited by Mönckeberg, found eleven cases among 1,317 autopsies on tuberculous individuals. Waller (17) in a recent paper reports three cases of tuberculous pericarditis among a total of eighty-three cases of pericarditis admitted to St. George's Hospital in London. There are no statistical tables available as to the occurrence clinically of tuberculous pericarditis in the various large institutions for the treatment of pulmonary tuberculosis.

The occurrence of cases of primary tuberculous pericarditis in which no other focus of tuberculosis can be found is exceedingly rare. Such cases have been reported by Simmonds (18), Scagliosi (19), Riesman (20), and recently by Hedblom (21).

The manner in which the pericardium becomes infected is not at all clear. In some cases infection occurs by way of the blood stream, in others occasionally by direct extension from a tuberculous mediastinal lymph node, or by its perforation into the pericardium. In the greater number of cases the pericardium is probably infected from the mediastinal lymph nodes by way of the lymphatics. The infection usually occurs first in the upper part of the pericardium where it is reflected on the great vessels. Here conglomerate tubercles are formed and from there they spread over the visceral and parietal layers.

The changes in the pericardium assume various forms. In the more chronic cases a fibrinous exudate is formed by which the two layers of the pericardium are glued together. This exudate is invaded by tuberculous granulation tissue which later becomes caseous, which sometimes forms a layer completely surrounding the heart. In some cases this caseous layer becomes liquified and absorbed, and is later replaced by a nonspecific granulation tissue. In such cases the end result is an adherent pericardium, the tuberculous nature of which may or may not be recognizable.

In other cases the formation of tubercles in the pericardium is accompanied by an exudate which is sometimes serofibrinous, frequently hemorrhagic, rarely purulent. The amount of the exudate may reach two litres. Musser (22) reported a case with 2,790 grams of hemorrhagic exudate. The layers of the pericardium become thickened, with the formation of ulcers on their surfaces. In some cases the fluid exudate is absorbed leaving a caseous layer which is pervaded by granulation tissue or by lime salts resulting eventually in an adherent pericardium or in calcification.

In the acute cases the exudate is also either fibrinous, serous, or hemorrhagic. When the exudate is removed small gray tubercles are found on the surface of the pericardium. In some cases there is no macroscopical evidence of tuberculosis and the tuberculous character can only be recognized microscopically. Thorel (23) cites the case of a seventy-one year old woman reported by Fromberg. In this case Fromberg found in one section a giant cell and in another a group of epithelioid cells resembling a tubercle. There was no other evidence of tuberculosis, but in the fibrinous exudate numerous tubercle bacilli were found. In this case there was evidently a massive infection with virulent bacilli. In the greater number of cases tubercle bacilli are seldom obtained from the exudate.

THE CLINICAL COURSE

The clinical course of tuberculous pericarditis may be entirely latent and its presence discovered at the autopsy. This is especially the case in the chronic forms with adherent pericardium. In the acute cases precordial pain often directs attention to the heart and the presence of a friction sound is discovered. Pain, dyspnea, and other cardiac symptoms are much less frequent than in rheumatic pericarditis where the myocardium is severely affected by the rheumatic virus. When fluid accumulates the changes found on percussion and the pressure signs over the region of the left lung are those which we have discussed.

(*To be continued*)

A Supplementary Note on Benzyl Benzoate

DAVID I. MACHT, A.B., M.D., LL.B., Phar.D. (Hon.)

Baltimore, Md.

In December, 1917, before the annual meeting of the Pharmacological Society, I announced for the first time my studies on the relation between the chemical structure and pharmacological action of the opium alkaloids on smooth muscle, and called attention to the fact that the antispasmodic properties of papaverin and narcotin were due to the benzyl component of their molecules (1). In February, 1918, before the regular meeting of the Society for Experimental Biology and Medicine, I announced for the first time my studies on the benzyl esters, benzyl benzoate and benzyl acetate which were the outcome of my work on the opium alkaloids and showed that these esters produced antispasmodic effects on smooth muscle and smooth muscle viscera in most respects very similar to those of papaverin (2). The complete reports of my work were published in the *Journal of Pharmacology and Experimental Therapeutics* for June and July, 1918, and almost immediately after the first announcement of the findings with the benzyl esters, benzyl therapy came into vogue for all kinds of spasmodic conditions of smooth muscle viscera, and since then various new benzyl compounds have been synthesized by various chemists, and benzyl therapy has extended to Europe, Asia, Australia, and South America.

Perhaps the most remarkable feature of benzyl benzoate therapy is the low toxicity of the drug, owing to its being converted into and excreted as hippuric acid, as I pointed out. Since the introduction of benzyl benzoate into practice, eight years ago, I am not aware of any important case of poisoning following its use in thousands upon thousands of cases.

One of the indications I gave for the therapeutic use of benzyl benzoate was in circulatory conditions, especially in angina pectoris and high blood pressure due to angiospasm, and I published a paper on the subject in this Journal in 1920 (3). About a year ago, Gruber (4) published a paper on benzyl benzoate in which he asserted that he obtained little or no fall in blood pressure in various animals after injection of the drug. Owing to a prolonged illness I was unable to reply to this criticism and indeed on serious consideration did not think it important enough, in the face of the enormous clinical experience to the contrary. Inasmuch, however, as the work of Gruber has found ready acceptance in certain quarters where more critical judgment was to be expected, I have repeated some of my original experiments with benzyl benzoate and other benzyl esters in regard to the effects on blood pressure. The results of these experiments agreed in every particular with the original observations published by me. Inasmuch, however, as my original statements have either been misunderstood or misinterpreted, it is deemed desirable to make a short further statement on the subject.

In working with benzyl benzoate on intact animals, as for instance on blood pressure, it must be borne in mind that this drug is very slightly soluble in water; hence the experiments must be made with carefully prepared emulsions. Because of its poor solubility and consequent slow absorption, and because the chief effects of benzyl benzoate are probably exerted, as stated further on, after its hydrolysis, observations on blood pressure must be carried on over *considerable periods of time*. One cannot expect an immediate marked fall in blood pressure after an injection of an emulsion of benzyl benzoate, although such effects are occasionally produced; more usually, however, a fall in the blood pressure is noticed from fifteen to thirty minutes or later after injection of the drug.

Although there is a difference of opinion as to the mechanism of the antispasmodic effect of benzyl compounds on smooth muscle, and although it has been claimed by Snapper, Grünbaum and Rümke (5) that such complicated synthetic benzyl products as akinetone act by virtue of the whole molecule, it seems most probable that benzyl benzoate exerts its action chiefly after hydrolysis and probably during its passage through the stage of benzyl alcohol to further oxidation and metabolization as hippuric acid. The low toxicity of benzyl benzoate is undoubtedly due to conversion into hippuric acid and has been shown to hold for benzoates and related compounds by Schmiedeberg (6), Minkowski (7), Mosso (8), Jacquet (9), and others. Benzyl alcohol has already been shown by me to have a marked effect on the blood pressure (10), and it is interesting to call attention to the apparently independent work of Jacobson and Laugier (11), who also found that benzyl alcohol produced a marked fall in blood pressure and who in agreement with me concluded that such fall in pressure was *due to a peripheral vasodilatation*. The vasodilator effect of benzyl benzoate, benzyl alcohol and a number of other benzyl esters studied by me can be demonstrated easily, on the one hand, by perfusion experiments, and on the other hand by experiments on surviving arterial rings and strips.

Fall in blood pressure after benzyl benzoate and other benzyl compounds has been noted by other experimenters and clinicians, as well as by me, as for instance Neilsen and Higgins (12), by Laubry and Mougeot (13), by Pal (14), by Giani (15), and other investigators. In studying the effects of drugs on blood pressure, even a tyro recognizes that several factors are concerned. A drug may be a powerful vasodilator and yet not produce a fall in blood pressure in certain persons, through its stimulating effect on the vasomotor centre, e. g., caffeine. It is one of the remarkable properties of benzyl benzoate, and to some extent also of benzyl alcohol, that in ordinary doses it is very little depressant, and indeed may be actually stimulating to the vasomotor centre, so that after injections of it in the intact animal, while there may be a marked vasodilatation, especially of the splanchnic area, the stimulating effect on the medulla

counteracts this dilatation and keeps the blood pressure at a pretty high level. Experimentally in such cases the vasodilator effect of the drug can be and has been repeatedly demonstrated by me by destroying the vasomotor centre by pithing the animal.

My original statement that herbivora react more rapidly to the administration of benzyl benzoate than carnivora has been repeated by me and confirmed. The human being is in my opinion more susceptible to the effects of benzyl compounds than dogs and cats and even rabbits. I have administered benzyl benzoate to a large number of patients and normal human subjects, and a decided, often very marked, fall in both systolic and diastolic blood pressure was almost invariably noted, as measured by Riva-Rocci, or Tycos, and also by Erlanger's apparatus, unless the arteries were enormously calcified.

It is a well known law of nature that *vis medicatrix naturæ* tends to restore abnormal or pathological conditions of living organs and tissues to normal, and drugs exerting their action in the *same* direction are generally more effective in such conditions than in the normal state. Thus antipyretics given to normal persons produce little or no fall in temperature, whereas when administered to animals with hyperpyrexia they cause a prompt fall in temperature. Again, digitalis given to a normal animal or human being produces little or no slowing of the heart or any other important pharmacological effect on that organ, yet when administered in cases of broken compensation and in dilated hearts its powerful tonic effects in such cases are universally known. So it is with benzyl benzoate. While in laboratory experiments *in vitro* and to a large extent in whole animals its antispasmodic properties can be easily demonstrated, none the less the relaxing effects of the drug are much more marked in cases of abnormally heightened tonus or spasm of smooth muscle. Benzyl benzoate produces a sedative effect on the intestines and in many normal persons thus tends to cause mild constipation, but its marked sedative action on the intestinal musculature is best seen in cases of *excessive peristalsis* such as in diarrhea (16, 17, 18). Again, benzyl benzoate can be shown *in vitro* and *in vivo* to have a quieting effect on the uterine muscle of normal persons, but this sedative action bears no comparison to the remarkable relief obtained with this drug in cases of spastic dysmenorrhea, a fact which is admitted by a large number of gynecologists (19, 20, 21, 22, 23, 24). So in regard to the effect of benzyl benzoate on the blood pressure. Its antispasmodic effects are exhibited best where there is a spasm of the vessels. In my own experience I have administered the drug to patients with hypertension in so many cases and have obtained such marked lowering of the blood pressure that to my mind there can be absolutely no doubt in regard to its value in such conditions. In this opinion I have been supported by numerous reports from various clinicians. Nor is there any doubt in regard to the value of this drug in cases of coronary spasm or angina pectoris, as found by my clinical experience and also by Spach, Babcock and others (25, 26, 27, 28).

In a study of benzyl mandelate which was prepared for me by Dr. D. Base, the antispasmodic property of the benzyl group was again demonstrated both on animals and patients (29); and recently, these observations were further confirmed and extended with the new benzyl compound betilon, a sulphonated benzyl by Hintzelmann, Joachimglu and Ohle (30).

I do not deem it necessary in this place to adduce further evidence of a clinical nature in regard to the value of benzyl benzoate in various conditions, more particularly in regard to its effects on high blood pressure. I think it, however, worth while to repeat a statement I made in another publication which seems to be appropriate in this place:

"There is a tendency on the part of some writers on 'rational therapeutics' to underestimate the value of repeated, careful, and accurate,—in other words, scientific,—therapeutic or pharmacological observations on man, and to regard all such data as of much less importance than data obtained from a few laboratory experiments on animals even by a tyro pharmacologist. A favorite habit of such critics is to spurn such clinical data as being the products of 'psychic suggestion' or as mere 'impressions' on the part of the observers, or as explainable by 'reflex' reactions. However ingenious, elaborate and technically masterly laboratory and animal experiments may be, if the data furnished by the same are utterly at variance with the therapeutic effects of a given drug as noted repeatedly by careful clinical observers, such evidence must perforce be accepted with reservation and regarded as inconclusive, or to say the least, incomplete; unless indeed the only alternative can be proven, namely, that the animal in question reacts to the particular drug entirely differently. If, however, the latter alternative cannot be proven, and if the same problem when approached by a different method of experimentation yields data in complete agreement with clinical experience, it is but logical to conclude that the latter method of experimentation is scientifically the sounder one and the results yielded by it are the more reliable ones" (31).

The bearing of this passage on the present subject is obvious. In conclusion I wish to cite a sentence or two from the classical work of William Withering in his *Account of the Foxglove:*

"There are men who will hardly admit of anything which an author advances in support of a favorite medicine, and I allow they may have some cause for their hesitation; nor do I expect they will waive their usual modes of judging upon the present occasion." . . . "After all, in spite of opinion, prejudice, or error. time will fix the real value upon this discovery, and determine whether I have imposed upon myself and others, or contributed to the benefit of science and mankind."

Dual Personality Apropos of an Unusual Case of Amnesia*

ALFRED GORDON, M.D.
Philadelphia

Consciousness of the ego concerning the psychic processes that are constantly taking place is a *sine qua non* of normal life. When this consciousness becomes disturbed and the ego can no more witness properly the mental activities, errors in ideas, in perceptions and in criticism will be the result. In psychoses in which the disturbances of consciousness play a most important rôle, the delusions are the direct result of the affected consciousness. Apart from psychoses, disturbances of consciousness may manifest themselves in many other conditions, among which amnesia is the most frequent. Here we find a great variety of disorders from the viewpoint of its etiology and pathogenesis.

Amnesia may be congenital, which is extremely rare. It may be caused by a traumatism. It may be due to organic cerebral lesions. It may follow acute visceral diseases or intoxications. Finally it may be associated with neuroses. As to the character of amnesia, the latter may be temporary or continuous; in the latter case it may become progressive. In the temporary form which is more frequent, it may be anterograde or retrograde. It may also be periodical. There are variations also in the intensity, in the quality and in the quantity of periods of mnemonic disturbances. Thus such an individual may lose all remembrance of his previous life; he possesses a new ego. In some cases the patient passes through two or more different short periods of life as two or more personalities, and one is not aware of the existence of the other. In another group of cases fragments of one personality are retained by the other: some acts committed during one state may be recalled in an other state. There are consequently cases in which there is no really complete interruption, but rather a continuity of consciousness which is only altered in its power of criticism at various periods. In still another group of cases there is a profound disturbance of general sensibility, and the entire person thus affected speaks of himself in the third person.

The majority of cases of dual personality recorded in the literature are examples of complete loss of normal selfconsciousness upon which normal stimuli have no effect. The characteristic feature of these lies in the fact that the psychomotor sphere is not inhibited in either state. Each personality in its own state acts in response to inner stimulations, and one state has not the remotest association with the other. It may happen that the lives the two personalities are leading are diametrically opposite to each other. As remarkable examples of such a state may be mentioned the case of Mary Reynolds (a case of double consciousness by Weir Mitchell), and the case of Reverend Hanna (multiple personality of Sidis and Goodhart). In the latter, consciousness was so profoundly dissociated that the two personalities he presented before the treatment was instituted, had individual systems of psychic states which carried on their functions in an absolutely independent manner. Striking examples are also described by Prince (1).

With few exceptions all the cases of double or multiple consciousness recorded in the literature present two characteristic features. One is, that at no special time is there a simultaneous coexistence of the two egos; one follows the other or they alternate. In Wilson's case (2) there were as many as twelve personalities; the transition of one to another was gradual or rapid, but only one at a time was in function. The other common feature is that at first there is total amnesia; one personality is unconscious of another; later, with or without treatment the gap separating the dissociated mental states is gradually getting narrower or filling up; some recollection of the past state appears in the mind of the patient in the successive state, so that after a long interval one state becomes aware of the existence of the other and the two egos may finally become synthetized into one personality. This is the usual process in cases of recovery. Those patients who do not recover present during their entire life the alterations mentioned of personalities with complete amnesia of each preceding state. As an exception to the first characteristic feature of double consciousness I may call attention to the case reported by me (3) in which the patient was aware of the fact that his ego was double and he called them number one and number two; they were extremely antagonistic to

*Read before the Philadelphia Psychiatric Society, March 12, 1926.

each other and one interfered with the activities of the other. An exception to the second characteristic feature of dissociated mental states is found in the case reported below. Here we find a complete and total inability on the part of the patient to recall a single event or even a fraction of occurrences which took place during an entire year, from October, 1923, to October, 1924. Moreover, some incidents which occurred during that period were of such a character that they aroused the strongest human emotions and continued so for a whole year and still the patient even at present, one and a half years after the return of her normal personality, has not the slightest recollection of them. We have in this case an example of the existence of a different personality during a period of a year with total amnesia of it and with no tendency towards filling the gap. The splitting of the personality occurred in this individual without any history of trauma, of acute infectious diseases, of an organic cerebral lesion and in the absence of any other special etiological factor. While the patient recovered her conscious ego, she has not recovered from her amnesia of facts and of her activities during the amnesic period. In such a case the prognosis is not favorable as it is contrary to the usual experience in cases of amnesia in which recovery occurs. The probabilities are that alterations of the personality will recur in the life of our patient.

Case.—Mrs. R. D. M. was twenty-five years old. She received her education in high school and art school. From seventeen to the age of twenty-one she occupied clerical positions. During that time she became extremely friendly with a young man. At the end of the second year of this warm friendship their relations were broken off. She became depressed, exceedingly nervous, could not sleep and lost interest in everything that formerly appealed to her. Her condition remained unaltered for an entire year. Upon the advice of her physician (Charles Manning) she took a position with short hours of service which she held for a brief period. In 1923 she entered the employ of a bank as a clerk and soon changed for a position in a news bureau which she held for a whole year. In 1924 she married.

It was noticed that within the two years before her marriage her disposition underwent a considerable change. She became domineering, refused to listen to reasoning and considered herself superior to anyone with whom she came in contact, including the members of her family. It was also noticed that during the last year before her marriage, that is from October, 1923, to October, 1924, when she was working in the news bureau she would remain frequently at the office during the evenings and would go to work also on Sundays and on all holidays. She would return home exhausted and go to bed at once. She would get up early, spend over an hour in the bathroom and start off for the office before eight o'clock. When reminded by her parents of the uselessness of doing late and very early work, she would ignore them and repeat the same actions and behavior. She avoided every member of the family and all her friends. The officials of the news bureau often spoke to her of the futility of doing unnecessary work at nights and on holidays, but she apparently did not pay attention to their advice. She was well thought of by the office force; her work was considered highly satisfactory and characterized by extreme precision and accuracy. Her acquaintances and friends, all her relatives were always fond of her because of her charming manners combined with her serious outlook on life, and particularly because of accuracies in her statements, remarks and dealings. She could be relied upon in every respect. She was considered exceptionally truthful. The parents and the officials of the news bureau did not interfere further with her unusual close attention to the work, but they were concerned about her tired appearance, pallor of the face, her poor appetite and progressive loss of weight. She absolutely refused to consult a physician or to relax in her application, claiming that the work must be done. Towards the end of 1924 the news bureau commenced to observe a shortage of money. Investigation at first failed to reveal the cause of it. Suspicion fell on our patient. It was shown that the sum of about two thousand dollars was missing. The parents were approached on the subject and while there was no direct proof, nevertheless they were threatened with arrest of their daughter. The patient was discharged. At that time her physical condition was extremely poor and for this reason her physician counselled not to question her on the shortage of money. Every effort was made by the parents to avoid publicity. At that time she met with an accident and fell, being considerably confused and frightened. She became exceedingly nervous, developed obstinate insomnia, would cry without provocation. The parents decided then to interrogate her on the shortage of money. She was unusually surprised at this revelation and became much depressed and was worried. She said she knew nothing of this occurrence. Moreover, she never heard of the news bureau and of her being employed there. All she recalled was that she worked last in a bank, but when told that she left the bank in October, 1923, and that she was employed by the news bureau from October, 1923, to October, 1924, she became perplexed. All the incidents concerning the character of her work and the extraordinary assiduity by working every day until late at night were pointed out to her. She showed considerable amazement. She showed special distress when told that she was accused of having appropriated money belonging to the news bureau. She could not believe that the accusation was genuine especially in view of her scrupulous honesty. She never knew of the existence of the news bureau and was particularly disturbed when told that she had been employed there a whole year. She had no knowledge of working there and of having done extra nights' and holidays' work. She had no recollection of the warning of her parents and of the officials against overwork. She was extraordinarily amazed and astounded when she was told of being married. She did not remember having seen the minister who married her; she did not recall having obtained a marriage license nor having roomed with her husband.

At present she knows nothing that occurred during the year from October, 1923, to 1924. It is only since the accident of the fall that she commenced to realize that there was a lapse of an entire year in her life and that she presented a different personality during that time. When questioned with regard to her married life it was singular to observe that she had no

knowledge whatsoever of the most emotional incidents connected with it. She remarked that soon after the accident she woke up in the morning and was painfully surprised to find a man in her bed. Indignantly she ordered him to leave; but when the situation was explained to her she broke down and cried. She knew the man for several years as a friend of the family, but she had no knowledge of having cohabited with him during an entire year.

A repeated examination made six months later reveals the same amnesia of one year's duration. She still cannot recall a single incident in her life during that period. No surprise questions nor the free association method could be of any assistance in this direction. She disclaims all knowledge of the amnesic year. She is much distressed over her inability to recall a single event, neither with regard to her employment, nor to her having lived with a man without knowing it. She became frequently depressed and was exceedingly anxious for medical assistance in order to bring back to her memory all that happened. She was perfectly lucid at time of examination, she showed no trace of mental disorder, she was free from delusions or hallucinations. Her judgment was excellent. Somatically she presented evidences of an exophthalmic goitre. A careful examination failed to reveal hysterical stigmata. While intellectually she could be considered normal, in the emotional sphere there were some abnormalities: she was indifferent; not easily aroused. She was honorable and devoted to her husband, but took no special interest in him, in his affairs, in his attention to her. Sexually she was totally indifferent, finding no response to her husband's advances or caresses. No man or woman could stimulate her by their friendship; she did not pay the least attention; she was not particularly aroused by gaining or losing a friend. No event of a striking nature stimulated her greatly as far as amusements were concerned. She liked to see good plays, but she never became enthusiastic over them.

The affection lavished on her by her parents was received with a great deal of indifference; gifts of the most delicate character presented to her were accepted with a pleasant smile but there was no enthusiasm. She treated her friends indifferently, apathetically. Although her personal appearance showed the most elaborate care in the details and she dressed in the latest fashion, nevertheless her attitude towards it was total indifference; there was a lack of voluntary personal element; it was evident that her actions were automatic. She was well posted on the events of the day, national and international, but there was no real or deep interest in the outcome of important occurrence affecting her country. She claimed being attached to her parents, but was eager in conversation to emphasize their faults and shortcomings. When one of her parents was ill, the little attention given by her was utterly lacking wholeheartedness and genuine sympathy. Her previous medical history presented nothing worth while as far as somatic diseases were concerned. No detailed account could be obtained from the parents concerning her emotional life or characteristics except the multiple controversies with her father and a sense of superiority that she always exhibited in dealing with her school friends and her relatives. Her viscera were normal. All biological tests proved negative.

In an attempt to analyze the occurrence of the amnesic period, otherwise speaking to understand the why of a whole year's flight from realities of life, one must bear in mind the patient's domestic situation, her relationship to her parents, her opinion of them and her general comportment and attitude, finally the incidents in her life. One recalls her constant controversies with her father, with whom she always had disagreements and misunderstandings, her sense of superior ability and knowledge, the belief that she did not have to be corrected or advised, her constant tendency to object and even to rebel. Evidently the patient's life was difficult, if not intolerable, because of the conflict between the desire for selfexpression and the sense of duty towards the parents. The emotional shock that she sustained in having been rejected by her suitor psychologically interpreted means unfulfilled wish; it has undoubtedly added a new element of dissatisfaction and intensified the intolerable situation. It is then not at all difficult to appreciate the patient's rebellion against the conditions imposed by ideals of duty. In spite of the latter, the ardent craving to get away from the intolerable situation was ever present. Up to the period of the amnesia she was living in a state of intense repression, but the protest and rebellion remained just as intense because of lack of a legitimate outlet.

The history of the patient's life since childhood shows that she belongs to the category of psychoneurotics. The amnesia which had developed is merely the expression of a neurotic mechanism set in motion for the purpose of carrying out the urge of the subconscious forces. Instead of a physical selfexpression, the protests and the rebellion found expression in an amnesic state during which the patient led the life of a personality which was real and desirable to her. For reasons that could not be overcome the patient is presently compelled to continue living with her parents. It means that she is compelled to meet the same difficulties and her intolerable situation, the potentialities of which remain unaltered. The renewed rebellion and the repressed protests do not find satisfaction. If she continues to be sorely tried she may again become amnesic.

Psychoneurotic individuals are highly suggestible, highly sensitive and highly emotional. While they do not present new phenomena which are not observed in normal individuals, their reaction, however, to all kinds of stimuli is expressed in a greater intensity and is reproduced with a greater facility and branches out in a most unexpected manner. The complex psychological states which are due to conflicts between instinctive emotional elements and environmental occurrences and which are being created daily and hourly in every human being, are in psychoneurotic individuals more numerous and more intense. Bearing this in mind the management of such individuals must have for purpose not only their adaptation to the environment but also to themselves. They must be shown how to unravel and lay bare the elements of the complex psychological states which are in constant conflict so that to fit them to face themselves. Our patient must be shown how to gain a better insight into her personal problems. It is only after this task has been accomplished that she will face her environment and not find relief from an intolerable situation by an attack of amnesia.

What Can Be Done to Reduce the Mortality from Carcinoma of the Rectum

ARTHUR A. LANDSMAN, M.D.

New York

While we cannot hope to conquer cancer until its cause has been discovered, much may be done to relieve symptoms, prolong life and even diminish the number of deaths from it, if we make intelligent use of the knowledge we already possess. All means at our command need to be enlisted to combat the disease, for it is a community problem which costs many lives, brings much misery and carries in its wake widespread suffering, not only to the afflicted but to friends and dependents. Despite specious reasoning and ingenious juggling of figures, the truth remains that cancer has been steadily on the increase in civilized races; this is borne out by the mortality tables of life insurance companies (1), reports of the United States Public Health Service (2), and extensive experience among private practitioners in various parts of the country.

Over one hundred thousand persons died of cancer in this country alone in 1921, and what is more significant, the death rate has shown an upward trend in the last twenty years despite a substantial decline from other diseases (3). It is given on reliable authority that forty per cent. of all cancers are found in the intestinal tract, of which five per cent. occur in the rectum (4), and as that organ is accessible to direct examination it is disconcerting to find that a large proportion of cases are only discovered when they are too far advanced for effective treatment (5).

It is hard to reconcile this with the progress which has been made in medicine in the past twenty years or more, and we are persuaded that the blame does not rest entirely with the medical profession, but that the public contributes to it in no small measure because of its ignorance of medical matters and its general lack of interest in public health problems.

It is safe to assert that a majority of people have little accurate knowledge of cancer and when they are individually concerned will often drift along until matters are brought to an acute stage; the thought of a medical examination brings up to them visions of pain, expense, loss of time from business, to which we may add the natural reluctance of some people to submit to a rectal examination. It is difficult to induce them to consent to it unless for the relief of some urgent symptoms which are generally absent in early stages of rectal carcinoma; a growth in that area may be well advanced before it will produce disturbances for which a person may consider it necessary to see his physician.

The remedy is clearly education of the public in the nature of intestinal cancer and the dangerous consequences of neglect and delay; it is only on this basis that we can make a successful appeal to reason. A campaign of this kind should be carried on in a suitable manner through newspapers, broadcasting by radio, posters and announcements by which large numbers may be reached, and on a smaller scale, through welfare and social health agencies which enjoy the confidence of the public.

But this will not suffice unless we are then prepared to see to it that the patient should receive the best skill and care which can be given him. That this does not necessarily follow becomes apparent on looking over the literature. We quote from a well known worker in the field: "The responsibility is not limited to the laity. . . . there is distinct evidence of procrastination and lack of complete examination by the physicians who were consulted first. This is particularly true of rectal examinations" (6). Again and again we find that people have been treated for bleeding piles in whom unmistakable signs of malignancy must have existed for some time. Cases are on record in which patients have been under observation during a considerable period for chronic constipation when a sigmoidoscopic examination would have shown at once that the visible portion of the intestine was obstructed by a malignant growth. It is by no means rare to find that a person who has been repeatedly x rayed to determine the cause of chronic indigestion has a neoplasm of the bowel within reach of the finger. Until we shall be prepared to make more frequent and more skilful rectal examinations, at least in people who have suggestive symptoms, we are in danger of overlooking a certain proportion of such cases and allowing them to advance into the hopeless class. The remedy is not only education of the public but a better understanding of the subject of cancer control and prevention on the part of those who guard the public health.

We venture to suggest constructive criticism along the following lines:

1. Improved facilities in the teaching of proctology. Those who are responsible for the medical education of the future physician should see to it that he starts with a fundamental knowledge of rectal disorders. It is not fair to expect that this be picked up unaided, nor should postgraduate instruction take the place of elementary training. All medical students ought to be given an opportunity to enable them to recognize the more common rectal affections, be taught the importance of proctoscopic examinations and the proper use of rectal instruments.

2. Establishment of rectal clinics in connection with all dispensaries and hospitals. It would seem that it is unnecessary at this late date to present arguments in favor of a proposition so plainly in the interest of public health and the advancement of medical science. But while many progressive hospitals both here and abroad have long maintained such special clinics, there are others who, because of their traditional conservatism, hesitate to take any step forward which is a departure from the order of the day. Experience has proved that the greatest progress in any branch of medical science comes with better opportunity for intensive study of special problems; such methods would stimulate the study of rectal disturbances, develop well trained men and encourage research along original lines.

3. Routine proctoscopic examination of all persons approaching middle life. Because of the slow and insidious growth of rectal cancers and their lack of early definite symptoms, it is impossible to make a diagnosis of some cases of carcinoma of the lower bowel unless patients can be seen in the preclinical stage. It goes without saying that if all persons of middle age could be induced to submit to a rectoscopic examination (which is simple and painless), many lives could be saved by timely surgical intervention.

4. Removal of precancerous lesions. It has long been known that benign tumors, ulcerations, chronic eczematous conditions, long standing piles, cutaneous tags, tracks of old fistulæ and other lesions about the anus and rectum have a tendency to undergo malignant change when subjected to chronic irritation and workers in this field have been able to produce carcinoma in laboratory animals by the use of certain irritant agents (7). It would thus seem that in the removal of such lesions it would be possible to prevent the development of cancer of this type, and here is the key to one of the most important methods of cancer cure—to treat the cancer before it develops. If we can awaken the public to the potential danger which lurks in the neglect of long standing rectal troubles, we shall be able to save the lives of many persons who are otherwise doomed to suffering and early death.

Treatment of Cancer of the Rectum

CHARLES J. DRUECK, M.D.
Chicago

Cancer of the rectum below the level of the pelvic brim and above two inches from the anus is best removed by a combined abdominal and perineal operation as first performed by Czerny in 1884. Various modifications of the original technic have been described because our method of approach cannot be constant, but depends rather upon the extent of the disease, the involvement of other structures and organs, the patient's age, sex and physical condition. Sometimes it is possible to bring the proximal gut down through the sphincter and attach it to the skin, thus preserving the anus in its normal location, but such a procedure leads to the danger of leaving *in situ* intestine or lymphatics which contain particles of malignant disease.

In all cases where the rectal ampulla is involved an exploratory abdominal section should be made through a liberal median incision.

Where cancer is limited to the colon or movable sigmoid and is entirely surrounded by peritoneum it may be lifted out of the abdominal wound. This operation is quickly performed and causes no great mutilation of the tissues. But where the growth extends below the promontory of the sacrum (the rectosigmoid junction), and is but partially covered with peritoneum, a complete removal through an abdominal incision is attended with many difficulties and mishaps and the combined abdominal perineal operation is unquestionably the best. It permits a careful examination of the liver and the lymphatics for metastasis and by closely noting the extent of involvement of the rectum and contiguous organs determines definitely whether continuity of the bowel to the anal region may be maintained or whether a permanent anus shall be provided. This operation offers the patient the best chance of ultimate recovery and freedom from recurrence. With perineal methods, even after the most complete and extensive removal possible, whereby recurrence in the immediate vicinity is reduced, nevertheless, new growths appear in situations beyond the scope of removal via the perineum. Postmortem examinations show that these recurrences are, 1, in the pelvic peritoneum; 2, the pelvic mesocolon; and 3, the lymph nodes situated over the bifurcation of the left common iliac artery. In all cases the infiltration of the parietal border of the pelvic mesocolon causes shrinkage of the pelvic mesocolon itself, whereby the pelvic colon appears to be bound down, a condition which readily explains the difficulty in obtaining a satisfactory spur when performing colostomy in an advanced case of cancer of the rectum.

From these observations it is obvious that the above mentioned structures constitute the zone of the upward spread of cancer from the rectum, the removal of which is just as imperative as is the thorough clearance of the axilla in cases of cancer of the breast if freedom from recurrence is to be hoped for.

The study of the spread of cancer from the rectum has led me to formulate certain essentials in the technic of the operation which must be strictly adhered to if satisfactory results are to be obtained, namely:

1. That an abdominal anus is necessary.

2. That the whole pelvic colon, with the exception of the part from which the colostomy is made, must be removed because its blood supply is contained in the zone of upward spread.

3. That the whole of the pelvic mesocolon below the point where it crosses the common iliac artery, together with a strip of peritoneum at least an inch wide on either side of it, must be cleared away.

4. That the group of lymph nodes situated over the bifurcation of the common iliac artery are in all instances to be removed.

5. That the peritoneal portion of the operation should be carried out as widely as possible so that the lateral and downward zones of spread may be effectively extirpated.

In operating for cancer it is important not only to remove the local tumor and such adjacent tissue as might possibly be affected, but also to remove as much as possible of the tributary lymph nodes. To do this necessitates the removal of the whole rectum, together with so much destruction of muscle and nerve tissue that a controllable anus is impossible, and an abdominal colostomy will usually give better results at less risk. Fagge (1) says the entire anal canal should be removed when the carcinoma has its origin in the rectal ampulla. Mayo (2) advises the removal of at least six inches of apparent sound bowel above and not less than two inches below the growth with all the surrounding fat and glands.

Excision of the rectum is one of the most formidable operations in surgery, entailing, as it does, the removal of practically the whole of the pelvic colon as well as the rectum, and a word regarding the practical anatomy will not be amiss. The pelvic portion of the sigmoid is about sixteen inches long and extends from the edge of the psoas muscle to the level of the third sacral vertebra. It makes a horseshoe shaped loop and has a mesentery one and a quarter to three and a half inches long. The length of the loop and also its mesentery is quite variable.

If colostomy is performed as a primary operation, to be followed later by radical removal of the diseased tissue, it allows thorough evacuation of the bowels and careful cleansing of the distal gut before doing the second operation.

Beginning two days before the operation our patient is given the usual preparation for a laparotomy. When he is anesthetized, the rectum is irrigated with formalin or bichloride solution followed with full strength peroxide of hydrogen.

The patient is placed in the Trendelenberg position and the abdomen is opened with a four inch incision in the median line. A liberal opening is necessary to allow working space. The small intestines are thoroughly packed back to facilitate a clear view of the lower sigmoid and rectum as well as to prevent unnecessary handling and encroachment of other parts of the intestines. The patient is then turned to the horizontal and the sigmoid is lifted out of the wound and held taught, thus bringing the sigmoid artery prominently into view. The peritoneal covering of the mesosigmoid is slit open close to the gut about two inches above the growth, and with a pair of blunt pointed scissors the incision is continued along about half an inch from the margin of the gut, thus separating the peritoneal wall from the vessels. This dissection is continued from the sigmoid back to the peritoneal flexion on the posterior abdominal wall and the ileum. The bowel is then laid over on the other side and the peritoneum similarly elevated on that side. The sigmoid artery is traced to its origin in the superior hemorrhoidal artery and just above this junction the superior hemorrhoidal artery is tied with two ligatures and cut between.

The superior hemorrhoidal artery is next tied in two places and cut between the ligatures. Care should be taken not to injure the middle sacral artery; by saving it the operation is almost bloodless.

In the female the left broad ligament should be detached together with the left ovary and tube. This having been done, the pelvic mesocolon, together with the adjacent strip of peritoneum on either side of it, is detached from the hollow of the sacrum as far down as the levator ani muscle. By keeping close to the anterior sacral ligaments, the cellular tissue containing the lymph nodes in that situation is detached with the pelvic mesocolon in one piece. This separation is continued downwards in the middle line as far as the sacrococcygeal articulation.

The sacral wound is now filled with gauze while a similar method of blunt dissection is carried out anteriorly by which means the bladder is detached as far as the prostate gland. Attention is now paid to the separation of the lateral aspects of the rectum and it is here that great care must be exercised to avoid injuring the left ureter which adheres closely to the peritoneum as it skirts the wall of the pelvis. When the ureter has been defined it should be carefully freed as far as the base of the bladder. On the right side the ureter need not be seen. The dissection is then carried downwards on either side and the lateral ligaments of the rectum are divided with scissors. In these structures the middle hemorrhoidal arteries are found, but seldom require a ligature. This lateral dissection is carried down to the upper surface of the levator ani. When the rectum has thus been freed on all sides as far as the points indicated, the bowel having been widely loosened should easily reach the normal anus without tension. If it does not do so the operator determines whether it is held by the mesosigmoid or by the bloodvessels. If the mesosigmoid needs further loosening it should be incised. The blood supply is next examined to be sure it is sufficient before proceeding. Arterial capillary pulsation must be felt in the parts. At the rectosigmoid junction is a portion of the bowel sparingly supplied with end branches. The lower sigmoid arteries supply from above, and from this point down the bowel is supplied by the superior hemorrhoidal, but these two arterial systems do not anastomose. If the superior hemorrhoidal is cut above its distribution to the rectum the lower end of the gut will not have sufficient blood supply and will slough, thus causing infection and death. This is a pertinent question in every case of cancer above the level of the floor of Douglas's pouch. When satisfied that the divided bowel will reach the anus with good blood supply the abdomen is well protected with pads, the bowel is divided with a cautery and the bowel ends closed with Lembert sutures. The rectum is now separated from the lateral ligaments and the whole of the detached structures are crowded down into the pelvis and covered with sterile gauze. Provided that the divided end of the colon has been firmly closed, considerable pressure may be made upon it from above without fear of leakage. The edges of the pelvic floor, and the abdominal incision are closed. The patient is then placed in the exaggerated lithotomy position and the detached mass is extirpated through the peritoneal route as has been described under cancer at the anus. The proximal end of the gut is brought out at the perineal wound.

If the proximal end of the bowel cannot be brought down to the anus it may be brought out of the abdominal incision as has been described in considering colostomy.

When the cancer is situated high in the sigmoid the continuity of the lumen of the gut by end to end anastomosis or lateral anastomosis has been followed by a very high mortality due to leakage.

In many cases rectal examination cannot determine whether or not the disease may be locally removable and an intraperitoneal exploration should be the first step of the operation.

Idiopathic Paralysis Agitans*

Report of a Case in a Man Thirty-Five Years Old

THEODORE C. FONG, M.D.
Washington, D. C.

(Concluded from Vol. CXXIII, No. 12, Page 803)

Freeman (17) of this institution reports, in his paper on the pathology of paralysis agitans, that in the two patients who died pathological examination of the brain revealed changes most marked in the substantia nigra. These changes consisted of degeneration of the ganglion cells with loss of pigment and replacement of glial tissue and a deposit of fat. There were moderate arteriosclerotic changes in the idiopathic case, but only minimal lesions in other areas of the brain in the case following encephalitis. There was also some inflammatory reaction about the mesencephalon in the latter case.

Therapy.—The treatment of paralysis agitans is practically entirely symptomatic, and very little, if any, has been added to its therapeutics since the first description of the disease. Parathyroid (18) was formerly employed, but has been discarded; Lundborg believed that this condition was due to hyposecretion of the parathyroids and therefore advocated its employment. Various drugs have been used with little or no relief. Those mainly employed are arsenic (19) in its various medicinal forms, drugs of the belladonna group, especially hyoscine (20 and 21), as antispasmodics, also analgesics and hypnotics. Hydrotherapy in the form of warm baths are somewhat beneficial in some cases. Electricity has also been used with practically no good results. The greatest relief from rigidity comes from the regular employment of passive movements. In closing, we must not forget that regulation of diet, rest, quiet, fresh air and sunlight aid in the treatment and we should note that excitement and fatigue should be carefully avoided.

REPORT OF CASE

Case.—J. P. M., a white male, single, aged thirty-five. He was admitted to this institution on April 18, 1923. He was transferred here from the United States Veterans Hospital No. 49 at Philadelphia. The transfer note which accompanied this patient states that he is quiet, causing no trouble; sits all day in the same place in the ward, pleasant and agreeable; shows no interest in any work, has parole, laughs much of the time in a rather silly manner.

Report from the director of the Red Cross service, Veterans Hospital No. 49: This man was usually very dull and sullen in appearance and behavior. He always said, however, that he was happy although his looks would never indicate this. He was hypoactive, content to lie around on benches and never could be interested in doing any work. He was very untidy in appearance and especially so in taking his meals. He had parole of the grounds which he never abused and he occasionally came to the Red Cross building for entertainments. He was never overly interested in these, however, and always looked rather bored.

The following history and physical findings were made at this hospital: The chief complaint was rheumatism. The family history was essentially negative. The patient was by occupation a truck handler, for a grocery concern, and he had worked steadily at this job for eight years except during the period of his service in the army, which was from July, 1918, to June, 1919. He was never overseas. With the exception of measles, mumps, chickenpox, whooping cough and diphtheria in childhood, no history of any acute or chronic illnesses could be obtained and particular care was taken to eliminate influenza and encephalitis as possible etiological factors. The only injury was a fracture of the nasal bones fifteen years ago.

About six months following his discharge from the service he states that rheumatism first appeared. In the interval between his discharge and his present illness he had returned to his former occupation of loading grocery trucks. He asserts that these pains came on rather suddenly and first became evident in his knees and later in both arms. Due to the pain and stiffness in his knees he was unable to get around very well and was later forced to give up his occupation. This pain remained more or less localized over his knees, but the pain in his arms involved the entire upper extremities and was quite sharp in character. His knees were swollen but not inflamed. He was treated at four hospitals prior to his admission to this institution. All this time he asserted that he had no tremor of any part of his body, and it was not until his transfer here that he noticed that he was becoming unsteady and that he had a jerky motion in his right hand which he was unable to control. This jerky motion he stated had gradually become more marked since his admission so that at the time

*Read before the Clinicopathological Society of St. Elizabeth's Hospital, Washington, D. C., February, 1925.

of examination he was unable to feed himself without spilling food about him. His rheumatic pains which were still quite marked on admission have entirely disappeared without treatment. He was admitted to the hospital building on February 17, 1925, for treatment of burns of both buttocks and, while on the surgical service an incidental diagnosis of idiopathic paralysis agitans was made. Prior to this time the case had been diagnosed as dementia precox (catatonic type).

Physical examination.—An adult white male, aged thirty-five, height five feet five and a half inches and weighing about 155 pounds, in bed in dorsal position with knees flexed and arms held over abdomen, elbows flexed, wrists extended and fingers flexed at metacarpal phalangeal articulations, the thumbs being held in opposition to the index finger. The lids were partly closed at times, the mouth was held opened and the facial expression was blank. The patient cooperated with the examiner, answered questions intelligently and coherently, had no delusions or hallucinations. He had slight retardation in responding promptly to questions, but after once initiating speech it became more free, but was rather monotonous in type. He exhibited some difficulty in sitting up from the reclining posture and he did not employ his hands in aiding himself to get out of bed, but rather pulled himself out. These motions were not free and easily done but appeared to be performed with some difficulty. When he walked his head was tilted forwards, his neck was held rather rigidly together with the muscles of his shoulder and spine and he was inclined to tilt his trunk forward and his knees were slightly flexed. Occasionally he tended to exhibit retropulsion. Skull and scalp were negative with the exception of a small scar over vertex of scalp.

The facial expression was masklike and stolid. The voluntary movements of the facial muscles were slightly more marked on the left side. The skin and sensation were negative except for slight acne and a moderate degree of hyperidrosis. The eyes had a vacant stare. The ocular movements and vision were normal. The pupils were unequal and slightly irregular, the left being larger than the right. Both were centrally placed and both reacted well to light and accommodation. The ears were negative. There was rather marked deformity of the nose resulting from an old unreduced fracture. The nasal septum was deviated to the left and there was a perforation most probably traumatic in origin in its lower anterior portion. The right nostril was larger than the left and within the right nasal cavity there was some ulceration and crust formation which was due to continual picking of it. The mouth was negative. The teeth were in good condition. The tongue protruded in the midline and there was a slight tremor. The pharynx was not injected and there was no apparent difficulty in deglutition. There was no speech defect but some hesitancy. The neck was held rather rigidly but was otherwise negative. The thorax was slightly asymmetrical, the right side of the chest being more prominent, the expansion was equal and there was a deep funnel shaped depression of the lower end of the sternum. The cardiovascular system was negative. Blood pressure 116-76. The lungs were negative. The abdomen and external genitalia were also negative. There was some tendency to muscular rigidity most marked in the muscles of the face, neck and back. There was no atrophy or paralyses. The socalled cog wheel phenomenon was present and appeared to be more marked on the right. The hand grips were good. There was an involuntary intermittent tremor involving the right hand, wrist and forearm which varied in intensity. At times it became more marked. It disappeared when the patient was sleeping and could not be controlled when awake. The hands were held in the pill rolling fashion, with the wrist slightly extended and the fingers flexed at the metacarpal phalangeal articulations, the thumbs opposing the index fingers. There were no tremors present in the other extremities. The knee jerks were exaggerated and this appeared to vary at times. The biceps and triceps were somewhat increased. The Achilles reflexes were hyperactive. The superficial reflexes were also increased. There was a suggestive bilateral ankle clonus. No other abnormal reflexes were present. The gait was not festinating in type, but was rather slow. The coordination tests were fairly well performed. The cranial nerve examination was negative. Sphincter control was normal. The laboratory findings: Eight blood Wassermanns were made, the third of these being weakly positive; the balance were negative. Three cerebrospinal fluid examinations were normal. The blood count and urinalysis were normal.

SUMMARY

This is a case of idiopathic paralysis agitans occurring in a white male of thirty-five who presents practically all of the cardinal symptoms and signs, and in whom no etiology for the disease can be definitely established. This case is being reported inasmuch as it is rather rare to see this disease occurring before the fifth decade of life.

Practical Therapeutics

Modus Operandi of Therapeutic Agents in the Treatment of Infections

JAMES W. WILTSIE, M.D.

Binghamton, New York

The general trend of thought regarding the modus operandi of therapeutic agents in infections is changing rapidly these days as we come to a better understanding of the physicochemical reactions in the body in health and disease and are able to study these reactions more accurately by improved methods and technic. The old idea was that drugs acted directly in destroying the infecting organism in the body, the unattained ideal being a drug which at one and the same time would destroy the invader and be harmless to the host. Today this ideal has been practically abandoned as the result of research work which shows that no drug remains in the blood stream in sufficient concentration to be bactericidal for more than a few seconds. It would appear that Nature resents these foreign bactericidal agents as much as she does the living organisms, and alters and eliminates them as rapidly as possible.

Nature's method of attack upon parasitic organisms is not by means of chemical agents, which might damage her own structures as well as those of the invader, but by a slower, more complicated and much surer method of warfare—the establishment of immunity. Any value, therefore, which may be attached to therapeutic agents in combating infection must be conceived to be the result of stimulation or aid in some other way of Nature's own defensive mechanisms, leucocytosis and antibody formation.

Benefit accruing from the use of dyes, salts, synthetic chemicals, colloids and vaccines, administered by mouth, subcutaneously, intramuscularly or intravenously, diathermy, radiation, counterirritation, hydrotherapy and massage, might all be the result in whole or in part of a specific or nonspecific immunity development. There is a disturbance of the *status quo* in the diseased tissues for the healing of which the treatment was applied, and we must assume that antigens are released, that complex molecules are broken down, and that as a result of this, antibody formation and leucocytosis are initiated.

What, then, should determine our choice of agent in any given condition, if there is any choice, and what should determine our method of application. The differences in reaction to these various agents variously applied are differences in degree only. We should be guided in our choice of agent and method of use by the following factors: safety, degree of reaction anticipated, relative trauma induced, degree of direct approach to the causative agent, and relative specificity.

The special circumstances surrounding certain cases obviously ideal for certain types of treatment are selfevident and require no defense as compared with other methods of eradication, e. g., surgical removal of diseased tissues. Direct approach rules here, and the trauma induced is insignificant in comparison with the benefit to be derived from this procedure.

Several therapeutic agents equally effective presenting themselves, we would naturally choose the one known to produce the minimum amount of reaction. Likewise in considering methods or agents of equal therapeutic value we would select the one producing the least degree of trauma.

As to the degree of direct approach to the causative agent, the nature of the infection, the nature of the agent to be used, and limiting factors inherent in the patient himself, will frequently automatically guide us in our choice. But when it is possible to choose, the order of preference would certainly be, direct application of the agent to the focus of infection, the intravenous route, intramuscular injection, subcutaneous injection and ingestion.

As to relative specificity of agents or methods we enter a more complicated field. We know that quinine shows a greater relative specificity for malaria than any other agent with which we are acquainted. Mercury, arsenic, bismuth and iodides seem to have a greater relative specificity for syphilis than other drugs.

In infections, with which this paper deals, eradication or cure by whatever means is the desired result. If the source of the infection is known, surgical removal or drainage may be possible. If the infection has existed so long that secondary foci exist, eradication of the original source *per se* is ineffectual. There are frequently cases, manifestly systemic infections, in which all attempts to locate the primary focus fail. In these cases our efforts should be to aid Nature in establishing an adequate immunity against the causal organism. Frequently, however, this organism cannot be identified. Any means therefore that we might have at our disposal of creating a specific or nonspecific resistance would be highly desirable, and if in so doing the foci of infection should become manifest it would be still more gratifying.

Nonspecific resistance has been accomplished by intramuscular and intravenous injections of various therapeutic agents. Intramuscular injections as a rule cause pain and trauma. The products of the local reaction probably act as antigens, toxins and endotoxins of the organism producing the systemic infection for which these treatments are given being present, undoubtedly exert some effect in producing specific antigens. Whatever may take place some immunity is developed and the patient improves. However, we may get a very unpleasant protein shock reaction as the result of the toxic nature of the products of the reaction. This protein shock reaction may also occur when certain substances are used intravenously in an attempt at nonspecific immunity development. Shock reaction is not necessary to the establishment of immunity and if possible should be avoided.

As a result of my observations while using sodium iodide intravenously in infections and allergies I have

come to the conclusion that sodium iodide acts as an antigen liberator, that ambocepter elaboration is thereby stimulated, that a complement fixation reaction occurs and that leucocytosis is thereby called forth, i. e., that the active presence of complement fixation stimulates leucocytosis and that the leucocytosis exists for the purpose of ingesting the end products of the complement fixation reaction as well as for combating the living bacteria. It might easily be conceived that these leucocytes as the result of having been called into being by specific complement fixation would themselves be specific against the causal organisms, and having ingested the end products of complement fixation would themselves possess an immunity against these organisms. Certain it is that an eosinophilia or a lymphocytosis called forth by certain types of infections suggest specificity.

My conclusions differ from those of other observers in that I believe leucocytosis is always secondary to and dependent upon the active presence of the complement fixation reaction—the evidence of immunity establishment. They, however, believe that leucocytosis precedes and has a causal relationship to the establishment of immunity. Nevertheless, we know that immunity exists independent of leucocytosis, and that leucocytosis is present only when immunity is actively at work as evidenced by the active presence of complement fixation.

Furthermore, during an acute allergic manifestation there exists a leucocytosis, as evidence of active complement fixation. We may consider this as an immunity reaction. Sodium iodide administered intravenously relieves the acute manifestation and the leucocytosis at once disappears. The antigen is still present, but the antibody formation has ceased as a result of desensitization. Therefore complement fixation ceases and the stimulation of a leucocytosis is lacking and our leucocyte count returns to normal.

Compared with the protein shock method of immunity establishment, with the intravenous use of dyes or antiseptics or with intramuscular injections of mercury salicylate, sodium iodide, by virtue of its powers of resolution, mild stimulation and lack of undue irritation produces a purer, more nearly specific antigen liberation than these other substances. Sodium iodide intravenously rarely produces a severe reaction, frequently barely perceptible, and yet immunity is established. The iodide in some way appears to alter the toxic end products to render them less toxic. For this reason alone sodium iodide should be the choice of agents when indicated. Being given intravenously the method also is that of the greatest degree of approach and least trauma.

However, sodium iodide does have certain limitations and definite indications which it is very important to observe. These limitations and indications are dependent upon the known therapeutic actions of iodides in the body. Primarily these are but two, namely, stimulation of all living protoplasm, and the promotion of a lysis and disintegration of all dead and dying protoplasm and all pathological exudates.

It may be appreciated that in acute infections and in septicemia sodium iodide would be contraindicated as it would interfere with Nature's attempt at localization. Furthermore amboceptor elaboration is stimulated to functional capacity by most acute processes, and any further stimulation might result in exhaustion. Some agent having a more pronounced bactericidal action and less power of resolution would be better here, possibly mercurochrome 220. Manifestly sodium iodide would be harmful in tuberculosis, as Nature's attempt here is to wall off the lesions and encapsulate them. Sodium iodide would destroy this wall and produce a local reaction which would merely result in extension of the lesion. The immunity reaction would be valueless as it is very difficult to establish an immunity against tuberculosis.

Sodium iodide should never be used following operative procedures, first, because it would produce a resolution of the lymph and exudates very necessary to primary union of tissues, and secondly, because of the danger of loosening a blood clot and producing embolism. For this same reason it should never be used in phlebitis.

Sodium iodide should not be used in massive infections even though chronic, as resolution takes place so rapidly that the blood stream is flooded with poisons and the patient is rendered seriously toxic. Under such circumstances immunity cannot develop as the severe toxemia seems to paralyze the defensive mechanism. This is apparent by leucocytosis failing to develop, or actual decrease of an existing leucocytosis.

The legitimate field for the use of sodium iodide in infections, therefore, narrows down to chronic and focal infections, systemic infections exhibiting a leucopenia as evidence of inadequate defense, and to diagnosis in obscure infections. In this field it is undoubtedly the agent of choice and the intravenous route the method of choice. We have the most direct approach, slight reaction, no trauma, an agent as nearly specific as it is possible to find, and, withal, a perfectly safe procedure. Indeed, in the amounts and concentrations given, sodium iodide in itself is nontoxic, moderately and generally stimulating, and whatever unfavorable reactions or accidents may have resulted from its use can safely be said not to have been as a result of the iodide or its method of administration, but from some fault in the technic of administration or disregard of its contraindications.

Sodium iodide is of undoubted value in locating focal infections when obscure. The release of antigens stimulates a complement fixation reaction and a leucocytosis which in turn react upon the focus of infection, producing tenderness, and simulating a local vaccine reaction. A general reaction also occurs. This trio of increased leucocytosis, local reaction and general reaction are usually all present. One or several injections of sodium iodide at two or three day intervals may be necessary for a diagnosis. Pain is frequently experienced if pus is confined, as in an apical abscess or an appendix. Soreness or tenderness occurs if the infection is not confined, as in tonsils or pyorrhea.

An acute appendicitis may develop as the result of breaking down lymph and leucocytic barriers surrounding a chronically infected appendix, thereby allowing the infection to extend. In these cases pain and rigidity may be absent, as the iodide absorbs the exudate in the tissues which as a rule produce the pain by increasing tension. Tenderness, vomiting and increased leucocytosis, however, are usually all present.

Sore tonsils and tender tonsillar lymph nodes would be diagnostic of chronically infected tonsils. A scratchy soreness in the pharynx would not indicate chronic tonsillitis as this sensation is a common symptom of iodism.

Although its physiological actions in the body are primarily the same whether given by mouth or intravenously, nevertheless intravenously it exhibits certain phenomena dependent upon its sudden accession into the blood stream which are never seen when given by mouth, so that in this respect it assumes the proportions of an entirely new therapeutic agent. Its action in promoting immunity is dependent upon its intravenous use, also its value in producing local and general reactions and sudden increase in leucocytosis. Its immediate effect upon allergies is also dependent upon the intensive action when used intravenously. Its stimulation of glandular activity is more pronounced when used intravenously.

Intramuscular or subcutaneous injection of any drug would not be as valuable a diagnostic agent as one intravenously administered, first because the local reaction at the place of injection would overshadow that at the focus of infection, and the antigens produced would be nonspecific—being those of the inflammatory products of the local trauma and not the liberated proteins from the focus of infection. Other drugs than sodium iodide intravenously, not acting so much as a solvent of existing exudates as an irritant producing nonspecific antigens, would produce a more powerful general reaction and at the same time a less marked local reaction at the focus of infection, thus obscuring the diagnosis.

When used intravenously symptoms of iodism, such as salivation, coryza, sore throat, and increased glandular activity, may occur after the first or second injection, but rarely after the third or subsequent injections. This may be due to acquired tolerance, desensitization, or the clearing of the tissues of metabolites. A reaction occurring after the first or second injection, no matter how severe, rarely influences me to discontinue treatment unless one of the previously mentioned contraindications are recognized.

In one case I observed a marked stimulation of the pituitary gland in a patient evidently possessing a tendency to hyperpituitarism. Several hours following the injection there occurred severe diarrhea, severe uterine cramps, and a tenesmus which enemas of sodium bicarbonate solution did not relieve, and was finally controlled only with codeine. Complete physical exhaustion followed. Two days later with considerable difficulty I induced this patient to allow me to give another intravenous injection. She finally consented and none of the previous symptoms were present.

The increase in leucocytosis observed after each injection of iodide is progressively less as the series advances. In one chronic case in which over one hundred consecutive injections had been given at two to four day intervals, the white cell count before injection was 7,200; the next day it had dropped to 5,000. The differential count remained practically the same. This shows that the iodide was actually producing an exhaustion of cellular activity through overstimulation. The progressive decrease in leucocytosis may in part be accounted for by the fact that there is naturally less antigen available for precipitation into the blood stream after each consecutive intravenous injection and in part to the fact that cellular activity is also less responsive to the same stimulation when repeatedly given.

I have observed three phases in the action of sodium iodide in chronic infections so frequently that I wish to call attention to them. The first is a sense of relaxation, well being and clearheadedness coming on within ten or fifteen minutes, before the patient leaves the office, due no doubt partly to the initial clearing of the blood stream of toxins, and partly to general cellular stimulation by the iodide. The second phase, coming on from two to four hours later, is the general reaction to the dissolved proteins and exudates which flood the blood stream at this time. It manifests itself by a vague stiffness, aching of muscles, headache, loss of appetite and at times a slight rise in temperature. The patient usually says he feels as though he were coming down with a cold. He feels grippy. The third phase, appearing two days later, is the result of the immunity reaction. The patient feels better in every way than he did before the injection. The local reaction may occur at any time from one half hour to several hours or even days after the initial injection.

Transplantation of Nerve Supply of Muscles.—J. E. Stewart (*Journal of Bone and Joint Surgery*, October, 1925) concludes from a series of experimentations with dogs that it is possible to reneurotize a paralyzed muscle by transplanting a block of active muscle containing its nerve supply into the paralyzed muscle, but the technical difficulties are so great that considerable doubt is thrown on its practical application. Thorough suture of the muscles was attempted in all experiments, using mattress stay sutures and whipping the edges of the muscle ends together with anterior and posterior rows of continuous fine silk. Better results might have been obtained had the extremity been immobilized in plaster of Paris for a time to prevent undue strain on the freshly sutured muscle. Several points were brought out in the work that are considered of value. It was noticed that dogs in which sartorius muscle had been resected and the rectus femoris paralyzed, got about perfectly normally after a few weeks, showing no limp whatever in walking. Experiments therefore seem unreliable.

The need of practising the utmost care in resuturing muscles which have been cut across during any type of surgical operation was clearly demonstrated. A muscle may not be cut transversely with the assurance that it will recover its function. If, however, it becomes necessary to cut muscles during a surgical procedure, care in accurately approximating their ends and thoroughness in suturing them gives a very good chance for their ultimate function.

Gynecological Operation in Insanity

ELLICE McDONALD, M.D.

Philadelphia

The responsibility in regard to psychotic women should imply something more than their custodial care and should encompass every known avenue of investigation in regard to their mental and physical condition. This is particularly true of the early cases, for there is the greatest hope of recovery.

In this connection, gynecological conditions are often of great importance. Gynecological abnormalities capable of producing symptoms are frequently found in the insane. One of the early workers in this field was Hergt (1) of Heidelberg, who, in 1870, wrote an excellent memoir on disturbance of the mind and diseases of women. He drew a distinction between causation of mental trouble by pelvic disorders and an increase in the course of mental disease, the result of pelvic disease with symptoms of hallucinations, erotic and lascivious inclinations. A correction of the pelvic troubles, according to him, relieved the patient of the superimposed mental excitement. The mental resistance was supposed to be lessened by the weakened condition of the body due to gynecological disease and the ground thus prepared for mental deviations.

An early American investigator was Alexander Skene (2), of Brooklyn, who, in 1878, studied the relation of gynecological disease and insanity in the Kings County Insane Asylum. He published his conclusions based upon five years' work and states his conviction that pelvic diseases, though giving rise to a great variety of nervous disturbances, are rarely the cause of insanity, but that irritation and exhaustion produced by uterine and ovarian disease are simply a predisposing indirect cause in those of already poor mental balance.

The first to make a really systematic investigation in this relation was Hobbs of London, Canada, who, in 1899, reported the results of five years' study and, of 217 patients, found that 185 had organic disease of one or more of the pelvic organs. Of these 185 patients, 171 were operated upon, nine were still to be operated upon and five were unsuitable for operation. In the 171 operations, the pathological conditions present (often several in one case) were: dysmenorrhea, seventeen cases; endometritis, eighty; subinvolution, ninety; hypertrophied cervices, thirty-five; laterated cervices, forty-four; cystic cervices, twenty-seven; polyp of the cervix, five; uterine fibroid, fourteen; epithelioma of the cervix, one; sarcoma of the uterus, one; retroversion of the uterus, fifty-five; complete procidentia, six; ovarian tumor, generally with disease of the tubes, thirty-one; perineal injuries, thirty-five; rectovaginal fistula, one; ischiorectal fistula, one. This give 444 diseased conditions in 171 cases. The operations performed were: curettage, 132; cervical operations, fifty-three; suspension of the uterus, fifty; ovariotomy, twenty-two; hysterectomy, twenty-one; perineorrhaphy, twenty-six; laparotomy for tuberculous peritonitis, two; operation for hematoma, one; myomectomy, two; giving a total of 309 operations. In regard to the mental health, seventy patients recovered from their insanity, in forty-three others there was marked improvement and, in fifty-four, there was no improvement: thus 133 of the 171 who survived the operation (there were four deaths), either recovered their mental health, or had it improved to a considerable extent.

This report of Hobbs is notable because it was apparently the first systematic study of gynecological disease in the mentally upset. About this time, 1897, Rohé, superintendent of the Second Hospital for the Insane of Maryland, reported the results of thirty-four operations, in thirty-two of which the tubes and ovaries were removed. He had eleven mental cures and nine mental improvements. His indication for the removal of the ovaries was hallucinations referable to the generative organs and increased at the time of menstruation.

There was a wave of ovariotomy that seized upon gynecologists about this time and the psychotic women did not escape. Three hundred cases of castration were collected in 1896 by Kroemer (3) who claimed that in seventy per cent. the results were favorable either in complete cures or amelioration. This statement is contrary to all later experience. In fact, there is no operation upon women which is so prone to be followed by mental disturbance as double ovariotomy. In the history of twenty-two postoperative psychoses in the experience of Taussig (4), over two thirds had had double ovariotomy; it was mainly the exciting factor, in others it made the condition worse, and in none was it beneficial. Such is also the experience of Manton, Raimann and Broun, all of

whom, with Taussig, did systematic research among those in mental hospitals. In Broun's twenty-three cases of ovariotomy only two patients recovered mentally after operation. In eleven cases of bilateral ovariotomy, with mental symptoms referable to the pelvic organs and accentuated by menstruation, Raimann (5) obtained no mental cures and, in only three, was there any diminution of the mental symptoms.

The excellent study of Broun (6) was a landmark in the progress of the understanding of the relation between gynecological and psychotic disease. In two notable papers, he reported the results of ten years' work in the female department of the Manhattan State Hospital. In all, 242 women had some form of gynecological operation and this number was less than five per cent. of the total number of women in the hospital during this time. There were sixty-two abdominal sections, fifty-one operations for displaced uteri and 129 minor plastic operations. Of all these 242 operations, 112 women were physically benefitted to a marked degree and 107 to a less degree. Five died, of which two deaths could be attributed to the operation and three to other causes. There were forty-three mental recoveries among the patients operated upon. In no instance was the mental condition of the patient made worse. He concludes that the belief that operative measures ever aggravate the psychoses is not in accord with his experience as he had no such aggravation in any of his cases. The same statement has been made by Manton in an experience of twenty years at the East Michigan Asylum and by Picqué of Paris from twelve years' experience. The rare occurrence of true and persistent psychosis following gynecological operation has been brought out by Rohé (7) who communicated with all the asylums in the United States and Canada and found that, in ten years, only twenty-five patients had been registered as becoming insane after gynecological operation. Broun states that the only postoperative insanities he had seen were cases of septic intoxication where relief from the sepsis brought a slow but steady improvement in their mental state.

Patients, whose mental disturbance might be largely influenced by the presence of pathological lesions, were those, according to Broun, who had benefit from surgical procedures. It was his effort to preserve one or both ovaries if consistent with the welfare of the patient. His conclusions are that, if operation is done, when needed, and the patient not subjected to an uncalled for castration, the mental condition is never aggravated by such a procedure; that there exist in insane asylums many who are suffering in an uncomplaining way from pathological lesions and that mental recovery quite frequently results after the correction of the lesion.

Other interesting reports are those of Henry (8) who reported twenty-eight cases with sixteen mental recoveries and eight mental improvements and one death, and Sauthoff (8), who examined two hundred women in the Wisconsin Insane Hospital and found that 103 had some gynecological lesion. In these two hundred cases only one had the mental symptoms begin after an operation.

The outstanding study of recent years in this branch of research is that of Taussig (4), from the observation ward of the St. Louis City Sanitarium, who examined 537 women and found that 252, forty-seven per cent., had some lesion in the pelvic organs "sufficient either to cause symptoms or to be in a position to cause them sooner or later." His conclusion is that gynecological disease is slightly more common in the insane than in the sane. In the three important groups, senile dementia, terminal dementia and paranoia, the number of women with pelvic trouble was about one third. In demential precox, about half of the women were diseased. About two thirds of the imbeciles were to be so classed, and, in the manic depressive group, the percentage of women with gynecological lesions was as high as seventy-four.

The dementia precox patients showed a large percentage with arrest of development. (This is also my own experience.) According to Taussig, it is more than probable that there is some correlationship between arrested development and dementia precox. In the group of imbeciles, arrest of development was also much more frequent than normal. Of special significance is the frequency of pelvic inflammatory trouble and its associated misplacements of the uterus in manic depressive psychosis.

As nearly as could be determined, 141 of the 252 women required some form of gynecological treatment, forty-seven were put upon conservative treatment and ninety-four fell into the operative class. At the time of operation his aim was to resect the tubes to prevent pregnancy and, if possible, to retain the ovaries.

The age onset of the psychosis was, in 107 women, forty-seven cases from twenty to thirty years, thirty-four cases from thirty to forty years, eleven cases from forty to fifty years, and nine from fifty to sixty years, or sixty per cent. from twenty to forty years, ten per cent. before eighteen years, and ten per cent. after forty years. His conclusions are that the manic depressive has a much greater frequency of gynecological disease (seventy-four per cent. compared with his average of forty-seven per cent.), that this increase is largely due to pelvic inflammatory disease and that there is a proportionately large percentage of mental recoveries in the form of insanity after operation. He draws attention to the necessity, as has every gynecologist who has studied the question, of a routine examination of all women received in the psychopathic wards.

In connection with the large percentage of arrested development, it is interesting that procidentia, or prolapse of the uterus, is infrequent in the woman who has never had children, as Kepler (10) was only able to collect seventy cases from the literature; yet by the circularization of insane hospitals, he was able to collect eighty cases of procidentia in nulliparæ mostly associated with imbecile conditions. The support of the uterus, like that of the intestines, depends mostly upon smooth muscle tone, so that this, no doubt, enters into the question.

Among those gynecologists who ascribe importance to such minor lesions is Schultze (10) of Jena who has drawn attention to the occasional importance of such minor lesions as displacement of the uterus and pelvic inflammation. He related cases to show the prompt and permanent benefit derived from appropriate treatment of the gynecological lesions, correction of the displacements, or provision for drainage secretions. He insisted upon the advantage of having a trained gynecologist on the staff of every hospital

for the insane and that there should be provision for an operating room. He recounts the experience of Bossi and others as to the value of immediate gynecological examination in the early stages of a psychosis.

The mentally disturbed woman thus has, in the opinion of these gynecologists, the right and necessity of special care and examination, not only on account of any possible gynecological lesion she may have, but also for the reason of the influence upon her psychosis. Gynecological lesions are quite frequently found, more frequently indeed than in the average run of gynecological patients. The following table is made up of the reports of various gynecologists and is an expression of the frequency of gynecological lesions in the insane. This table includes only the gynecological lesions requiring treatment if these had occurred in the sane.

FREQUENCY OF GYNECOLOGICAL LESION

	No. of Cases	*Lesions*	*Percentage*
Broun	700	543	77
Manton	100	81	81
Lawrence	100	84	84
Hobbs	220	188	85
Clause	554	..	15
Danilo	200	138	69
Hall	554	220	38
Taussig	527	252	47
Picque	..	..	89
Ripping	100 (autopsies)	33	33
Davenport	387	361	92
Sauthoff	200	103	50

Tomlinson (11) states that, of 937 insane women admitted, 233 had some menstrual disorder, 443 had leucorrhea, 408 had uterine displacements and in these 222 had adhesions binding down the uterus, seventy-nine had disease of the ovaries, 337 had lacerations of the cervix, 424 had lacerations of the perineum, 238 had cystocele, and 229 had rectocele.

If a collection of the statistics is made of such series that allow of exact deductions, 3,664 insane patients, examined by competent gynecologists, had gynecological lesions in 2,086 instances. *In other words, in this large collection of insane women, there were gynecological lesions capable of producing symptoms in about sixty per cent. of the cases.* It is to be presumed that these gynecologists were competent to recognize gynecological lesions when they found them, and, in those cases where the authors are known to me, my opinion of their ability is of the highest. It is to be expected, inasmuch as the gynecologist was called to the insane hospital on account of his special knowledge and in a consultation capacity, that he may be presumed to be a man of experience and judgment. So, it thus may be taken as proved that, in the opinion of competent gynecologists, sixty per cent. of insane women have gynecological lesions which require treatment, *per se,* on account of the gravity of the lesion, regardless of the influence upon the psychosis. In my experience in the wards of the Philadelphia General Hospital and in private hospitals, the frequency of gynecological lesions in women with psychotic disturbance is as great as that of the collected statistics, sixty per cent., and, indeed, it is my opinion that if a very careful examination is made from the point of view of influence upon the vegetative nervous system, more than this percentage will be found. This does not mean, by any means, that all these women should be operated upon, nor have I been able to find in the psychotic patients the very large percentage of infection that was reported by some investigators.

Operation upon the insane has little evil results if not mutilating and if done for definite lesions after the patient has been put into the best physical condition. It is true that the insane bear operation rather poorly and have a slightly higher mortality on account of conditions—1, their upset metabolism, and 2, the difficulty of postoperative care from their lack of cooperation and difficulty of management.

Mental psychosis, as a result of surgical operation, is at the present day not a common occurrence. In former years, when the postoperative treatment was less intelligent and there was much more intoxication from poorly given anesthesia, prolonged operation, free use of drainage and lack of detoxicating measures after operation, there was much more postoperative insanity. The free use of purgation, restriction of water, the frequency of abdominal drainage, and absence of narcotics was the custom in former years and these all combined to cause intoxication and disturbance. Dr. John G. Clark has told me that he used to see postoperative insanity much more frequently in former years under the old conditions, when he was Dr. Kelly's assistant, than he sees at the present time.

Postoperative psychosis is relatively very uncommon. Mitchell (12), in a study of 344 cases of postoperative neurasthenias and psychoses, found thirty-one out of 222 women with disturbance. Of these, seven were actual psychoses and five followed ovariotomy or hysterectomy. Taussig has drawn attention to the coincidence of ovariotomy and postoperative insanity. He has seen twenty-two postoperative insanities and of these fourteen had double ovariotomy and, in some, it was clearly the exciting cause, where, in others, it made the mental disturbance worse. In Mitchell's collection chosen from 344 cases of mental or nervous disturbances, of twenty-nine cases of psychoses or neurasthenia in females following operation, thirteen operations were ovariotomies. There were only two males in the thirty-one cases reported. Of these twenty-nine cases only seven had psychoses and the rest had neurasthenia, and, of the seven psychoses, no record is given of the duration or final result, except in one who died in mania, but from a study of his tables not more than three had a permanent psychoses. A classification of the time of onset is made by Regis (13) who divides these cases into those coming on immediately after operation and anesthesia, those coming on later and due to septicemia and shock and those coming on after weeks or months and due to asthenia from prolonged illness or lack of internal ovarian secretion.

In a consecutive series of 1,300 gynecological operations Kelly (14) found that no less than fifty cases manifested some well defined change in disposition, irritability, depression, suspicion, and other symptoms, which usually vanishes in a few days; but, in about 1,600 operations, there were forty severe cases with more permanent symptoms of mental disturbance. Of these, sixteen followed double ovariotomy and three followed removal of one ovary alone. He has no records of the number who did not recover mentally, but of fifteen patients from his private hospital thirteen recovered and remained well

while one became persistently insane and one remained mildly demented.

The character of the operation apparently has an influence in two ways, first, in regard to the abstraction of ovarian secretion, and second, from the amount of intoxication and metabolic disturbance caused by the operation. Ovariotomy is more likely to cause postoperative mental disturbance than any other gynecological operation and Urbach has reported five cases after 106 gallstone operations. At the time these gallstone operations were done, drainage of the gallbladder, a most disturbing procedure with prolonged convalescence, was much more frequent than at the present time. Ophthalmological operations are also among the surgical procedures more frequently followed by postoperative psychosis and this form of psychosis is more frequent in children, old people and hysteropathics.

The probability of recovery is high and it is to be expected that in at least three quarters of the cases of postoperative insanity the patients will recover their mental health. All forms of psychoses are found, exactly as in puerperal psychoses, but the most frequent are the acute hallucinatory confusional insanities or confusional psychoses with motor delirium. These designations of the psychiatrists are merely descriptions of mental symptoms and in no way describe any underlying pathological or cell change.

Most surgeons and psychiatrists believe that, when any postoperative insanity occurs, there is an underlying psychotic tendency and that the surgical procedure merely "pulls the trigger." This is simply begging the question as to the causation and it is quite probable that anesthesia and operation may in themselves produce a psychoses. Of course, it is true, as a physiologist who had been through a trying experience in the war has said to me, that "if there is stress and mental and metabolic disturbance enough, anyone can go crazy, but some people go crazy easier than others." Some achieve psychosis under local anesthesia and some under gas for tooth extraction, but generally it is the operation producing most metabolic disturbance which produces most postoperative psychoses.

It is of interest to note from the work of Overton, Pahl, Traube, Warberg, Weisel and a number of other investigators, that anesthetics in themselves produce a decreased cell permeability and decreased conductivity and Clowes has shown that anesthetics produce an effect closely comparable to calcium chloride and that both actions are referable to the alteration in the interfacial film. This can be demonstrated in the nonvital systems and an emulsion in a glass beaker can be anesthetized. We have found that decreased cell permeability and decreased cell conductivity are associated with vagus preponderance, and that vagus preponderance exists in four fifths of the cases of mental psychoses. Shock is also associated with vagus preponderance. So that, in surgical procedure there is an increase of vagus preponderance which, added to an already great preponderance, may produce such cell changes as to induce postoperative psychosis in one so predisposed.

The probable train of circumstances in postoperative psychosis is that a patient with vagus preponderance is increased in her preponderance by the anesthesia and operative measures and has not the measure of recovery seen in patients with normal balance. The frequency with which postoperative psychoses give a history of extreme apprehension, worry and fear before the operation is very suggestive of vagus preponderance as these are frequent symptoms of, and in themselves, produce vagus preponderance. This explanation might be extended to other cases of psychoses other than postoperative, but, in most of these others, the exciting cause has not been as well studied by the research in cell changes. Anesthetics and narcotics (the lipoid solvents) have been well studied in regard to colloid changes, so that it is possible to say what their action will be upon the human colloid cell and to show that this action coincides with the explanation given by us upon the basis of the vegetative nerve balance as an expression of cell changes. Other poisons, such as tetraethyl lead, syphilis, alcohol, etc., will also produce psychoses and this suggests that all psychoses are due to toxins or poisons which produce changes in the cell membrane and so cause deviation from normal of conductivity, permeability, viscosity, surface tension, potential differences to alter bioelectric variation. All these are essentially expressions of alteration in the colloid structure and Freundlich (15) has shown that, in coagulation of negative suspensoids of colloids, those of high valence, like calcium, magnesium and aluminum, have a much higher coagulating power than those of the low valence, like sodium and potassium, and higher than would be expected from the increase in charge. The adsorption to the surface film decreases more rapidly than would be expected from the increase in valence. But this action does not depend upon inorganic ions alone, but some organic ions have an exceptionally strong coagulating action. The anion of salicylic acid coagulates the positively charged aluminum sol much more intensely than the anion chloride, and the cation of morphine chloride has a much stronger coagulating action upon the negatively charged arsenic sulphide sol than has the cation of potassium. So that it may be seen that these researches of the colloid chemist are not idle abstractions, but directly applicable to such substances as narcotics and anesthetics, and give an explanation of the mechanism of their action upon the cells of the colloid human body.

These changes in the cell are directly indicated by changes in the vagus sympathetic balance. For example, blood pressure is higher in sympathetic preponderance and low in vagus preponderance; but calcium chloride produces a fall in blood pressure accompanied by marked cardiac irregularity. This fact does not depend upon our own statements alone, but has been amply confirmed, most recently by Major (16) who also observed that the irregularity was overcome by potassium chloride.

Calcium chloride, according to our researches, produces vagus preponderance which is an expression of decreased cell permeability and potassium chloride acts as a sympathetic stimulant, producing increased cell permeability and conductivity, so correcting the action of the calcium, hydrochloric acid and ammonium chloride (all of which produce acidity and vagus preponderance and reduce blood pressure as does the parathyroid extracts of Collip). All of these in our experience produce decreased smooth muscle reaction and vagus preponderance.

So that in the study of postoperative psychoses, it is possible to describe the action of the anesthetic and the shock in terms of cell changes and give a plausible explanation for the mechanism of the production of the disorder. This explanation fills the gap between the cause (the operation) and the terminal result (the psychosis), and this method is possible of application to any diseased condition or process of the human body. Symptoms should be explained in terms of cell changes and research should concern itself with vital processes instead of terminal or end results of disease. Until it does so, medical treatment will fail in its function because it will not be based upon any clear understanding of the action of the body cells or of the action of medicinal agents put into the body. The practice of medicine has been a rule of thumb method, but it is possible by applying the principles of colloid chemistry to get a reasonable explanation of old approved methods and open a wide vision of the application of new therapeutic procedures.

In the study of psychosis in the female, Bossi (17) of Genoa has opened a very interesting field. He believes that even slight alterations in the female genital apparatus may lead to mental deviation. Among other conditions he draws attention to suicidal tendencies and believes that half the suicides in women arise from gynecological causes, especially at the times of puberty, the menstrual epoch, pregnancy, puerperium or the menopause. These different physiological episodes are not the causes of suicidal tendencies, but serve as an opportune cause in an individual who has a psychotic tendency. He also believes that minor gynecological lesions, like retroversion, may produce conditions influencing a psychosis and that their surgical cure often benefits the mental condition.

His results were investigated by Ortenau (18) who went to Bossi's clinic and gave the details of seven cases of mental disorder which subsided under gynecological measures. Bossi's aim is restoration of normal conditions and claims that when these conditions are corrected, the psychic disturbance usually subsides. He pleads for the necessity of a gynecological examination in every case of mental disease, especially before committing any woman to an insane hospital. He also insists that gynecological examination should be a routine measure in every crime committed by a woman in the period just preceding or during the menses. This would certainly, he declares, prevent many errors in justice.

(*To be continued*)

Puerperal Infection: A Study of an Etiological Factor

DANIEL H. BESSESEN, M.D.
Minneapolis, Minn.

Puerperal infection has been recognized since the earliest history of medicine. Those names which Lea's (1) careful study have associated with the advance of knowledge on this subject are but a few of the long list of men—earnest, courageous workers all—who have given much of their time and work, some their lives, in an effort to solve this age old problem. It is only recently (1773) that any control has been obtained on what has been an inevitable, hopeless, fearful disease. Charles White's method of delivery in separate apartments, isolation from fever cases, and disinfection of rooms with brimstone dropped the terrible mortality to within short range of our present control. Gordon of Aberdeen (1795) demonstrated its infectious nature. The further light shed by Oliver Wendell Holmes (1843) and finally the excellent and careful studies of Semmelweiss (1847) have reduced to the present morbidity and mortality this disease which was not clearly understood until Pasteur (1879) related puerperal infection to bacterial organisms.

The more recent work by R. Koch, Doleris, Fraenkel, Döderlein, Krönig, Menge and others have made fairly obvious and more certain the maze through which our predecessors were wandering.

OCCURRENCE

The number of cases of puerperal infection which occurs in any region, institution or practice is dependent upon the criterion which is accepted as the standard of fever. After ruling out other infections, and determining that any fever is due to some inflammatory disturbance—toxemic or infectious—of the genital system during puerperium, the temperature elevation taken as the highest normal in a way determines the percentage morbidity. A Copenhagen hospital, taking 99.8° by rectum as the highest normal, has a morbidity of 46.0 per cent. Others—Paris clinic, Baudelocque and Kiel—with 99.8° by mouth as standard, have 11.72 per cent—15.9 per cent. morbidity. The Rotunda, Queen Charlotte (London), St. Mary's (Manchester), Vienna, Montreal, Sloane (2) with 100.0 as standard have from 6.0 to 22.9 per cent. morbidity. The Paris clinic, Basel, Strasburg, Munich, Wurzburg, Buda-Pesth with 100.4° standard have a morbidity of 8.94 per cent. to 15.8 per cent. The Sloane (3) Hospital in New York with an arbitrary standard of 100.6° shows a morbidity of 1.75 per cent. for the first twenty thousand cases and of 0.485 per cent. for the last eight thousand cases.

One would expect that the higher the accepted standard, the lower the morbidity would be, and in like manner the higher would stand the mortality rate among the morbid patients. There is observed a mortality of 0.09 to 0.08 per cent. among all cases and 2.0 per cent. to twenty-five per cent. of morbid cases depending upon the elevation of temperature accepted to the criterion of puerperal infection.

Some authors rule out of their figures all cases which do not contract the fever in the hospital; some rule out those cases which have been sent into the hospital after delivery outside; others include all types of puerperal infection cases, no matter what their

origin or derivation. So these figures are rather confusing. It is well perhaps to know that on the average, one in four hundred (4) (5) maternal cases results in death from puerperal infection: that in the United States an average of eight thousand die annually from this cause; in England and Wales, three

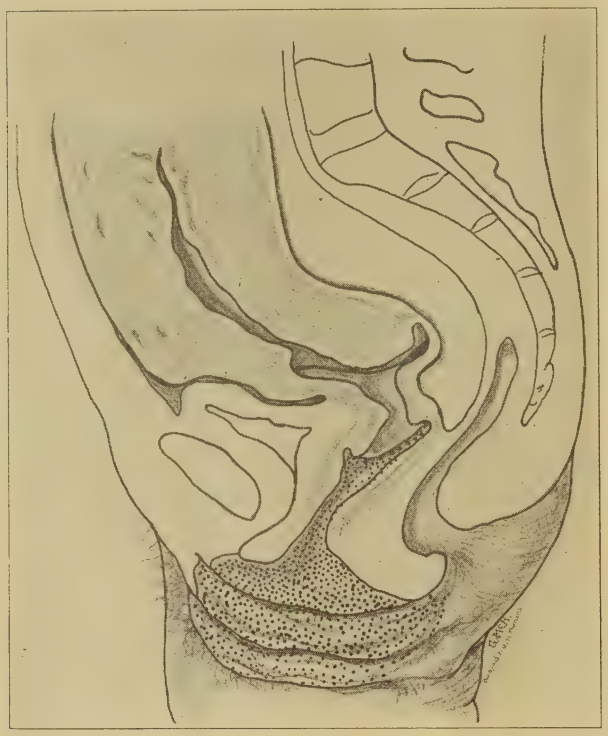

FIG. 1.

to five thousand; in Germany six thousand; and approximately ten times this number recover with serious after results. From 24.6 per cent. to eighty-three per cent. of all maternal deaths from childbirth are due to infection—varying with the region, the surroundings, the education of the peoples and other etiological factors (6) (7) (8) (9) (10) (11) (12) (13) (14) (15).

In reviewing a series of 936 obstetrical cases entered into Asbury Hospital, Minneapolis, relative to puerperal infection, the definition of puerperal infection stated by the British Medical Association is the accepted standard—a temperature of 100° by mouth on any two days from the second to the eighth inclusive, if arising from inflammatory change in the genital canal is puerperal infection. These cases were admitted into the hospital from January 1, 1924, to April 1, 1926, and of them 119 (12.71 per cent.) showed puerperal infection according to this definition.

Comparison made with the etiological factors described in the literature (4) (5) (7) (9) (12) (16) (17) (18) (19) (20) (21) (22) (23) (24) (25) (26) (27) (28) (29) (30) (31) (32) (33) (34) (35) (36) (37) (38) (39) shows that the length of first stage ranged from forty minutes to ninety-eight hours and ten minutes; second stage from eight minutes to forty-seven hours and twenty-five minutes; third stage, from one minute to six hours and thirty minutes; interval between rupture of membranes and termination of third stage, from one minute to forty-eight hours; fifty-seven girls, sixty-four boys, eight stillbirths; mothers sat up on the sixth to twenty-sixth days postpartum; Crede expression of the placenta in all but nine cases; large hemorrhage in ten; uterine packing in two; manual removal of placerta in five; vaginal examinations in eighteen; low forceps in thirty; medium in eight; high forceps in five; version in one; blunt hook in one; contracted pelvis in one; lacerations of perineum first degree in thirty-two, second degree in eighteen, third degree in one, repair of old laceration in two, episiotomy in thirty-seven, two of which had additional lacerations; retained membranes in one; ruptured uterus in one; one fetus was dead three weeks before delivery; anemia was concomitant in one; three mothers had associated abnormal pernicious vomiting, bronchitis and chronic scalp trouble respectively. Bruising and constipation were not carefully investigated but were commonly present.

This then leaves unexplained the etiology or cause of sixteen cases—that is, there was no apparent error in preparation of the patient, no operation, no operative manipulation, no accidents of labor, no foci of infection in the patient's body. Infection in these sixteen cases must in some way have gained entrance to the uterus. It is to seek an explanation for these cases that this study is advanced—to determine a

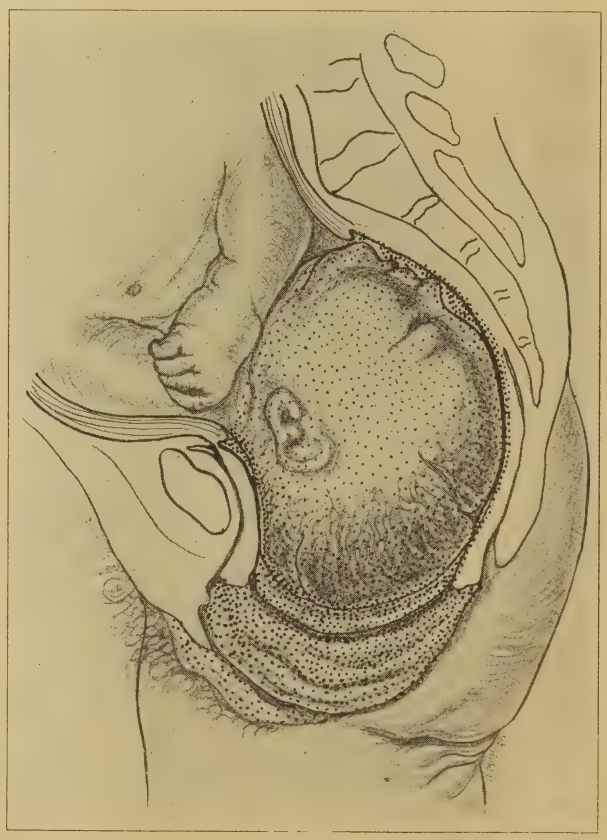

FIG. 2.

method of entrance of the bacteria into the uterus which may apply not only to these sixteen cases but to cases with other etiological factors concomitant. The thought advanced is that the usual mechanism of labor, especially the second stage, conveys bacteria

from the vagina into the uterus. It is a fact that bacteria are present in the vaginæ of a variable percentage of women (Fig. 1). Numerous researchers (4) (6) (8) (18) (21) (23) (40) (41) (42) (43) (44) (45) (46) (47) (48) (49) (50) (51) (52) (53) (54) (55) (56) have found bacteria in

Fig. 3.

the vagina; they are found in thirty-five per cent. of the vaginæ of normal women (8) (43) (44) (58); streptococci are found in from four per cent to fifty per cent. of vaginæ of normal women (42) (46) (59); in forty per cent. to fifty per cent. of pregnant women (42) (60) (61); in ten per cent. to seventy per cent. of vaginæ of women in labor (21) (42) (60); and in thirteen per cent. of vaginæ of women during puerperium (62). Haemolytic streptococci are found in thirty-three per cent. of vaginæ of normal women (55) (63); in one per cent. to fifty per cent. of pregnant women's vaginæ (40) (64); in the vaginæ of five per cent. to fifty per cent. of puerperal patients (55) (65) (66). Of those patients who had no streptococci in the vaginæ, in only four per cent. does fever develop, in eighteen or 18.7 per cent. (46) (41) of those with nonhemolytic streptococci does fever develop, and in seventy-five per cent. of those with hemolytic streptococci in the vaginæ does fever develop. The close relationship which exists between the figures concerning the presence of bacteria in the vagina—in normal, pregnant, parturient and puerperal women—and the actual appearance of infection in puerperium would indicate that the vaginal flora is the etiological factor in a large number of our present puerperal infections. The sixteen cases in this series demonstrate that the bacteria have some means, other than that found in the literature, of gaining entrance into the uterus.

The question is, then, how did these bacteria gain entrance into the uterus? The mechanism of the second stage of labor is in itself an important etiological factor in introducing these bacteria from the vagina into the uterus. On the one side is a culture tube, the uterus, on the other is an infected surface, the vagina, from which a smear is made by the fetus, which is wiped down over the infected surface and carried back into the culture medium, the uterus, where the subsequent growth of the bacteria gives rise to the fever indicative of infection. On analyzing the mechanism of delivery, it is evident that during uterine contraction, the cervix pulls away exposing the presenting point of the fetus. As dilatation becomes more complete, this presenting point is contaminated by the vaginal mucosa with which it comes in contact (Fig. 2). This is more marked when dilatation is complete and pains of a bearing down nature appear. At this time, the head of the fetus is forced down into the bulging perineum, while the cervix and lower uterine segment are retracted by that action of the uterus which is characteristic of the second stage of labor (Fig. 3). During relaxation the perineum forces the head back and the relaxed uterus allows the return of the cervix and lower uterine segment to their original position. Thus the contaminated

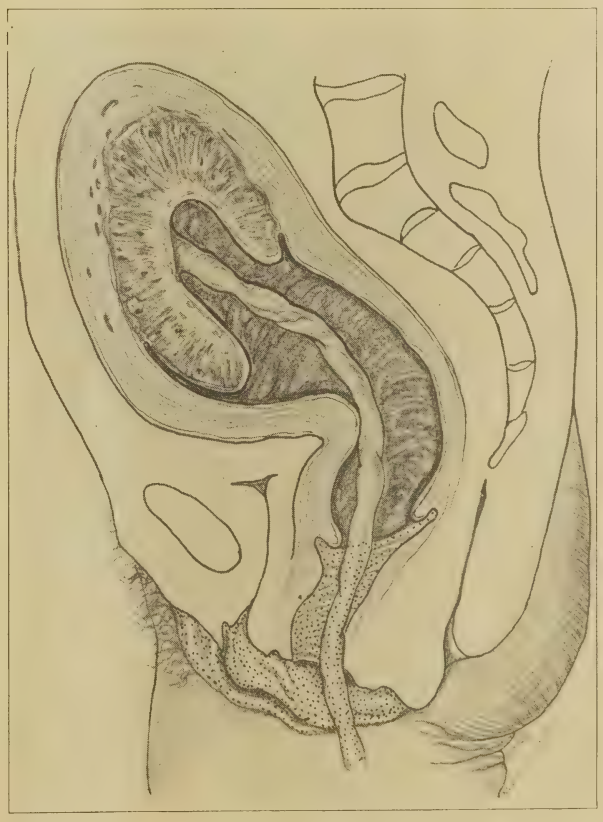

Fig. 4.

head, either covered or not covered by the membranes, enters the uterus. This process is repeated as long as the second stage lasts, and so it is that in long labors infections are more common and more severe, often fatal. With each downward descent of the fetus into the vagina, a higher point of the fetal

surface is contaminated by the bacteria which have previously been drawn into the uterus, and when the fetus again rises into the uterus, a higher point of the uterine interior is contaminated. Infections may occur with short second stage, where virulent bacteria are present in the vagina.

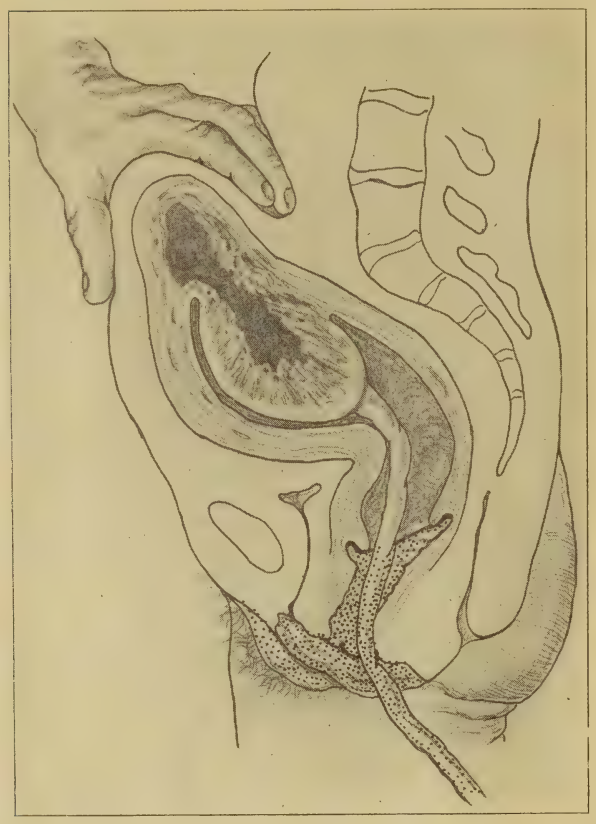

Fig. 5.

This mechanism (Fig. 4) also pertains to the Credé expression of the placenta, for here pressing the hand down on the large relaxed uterus allows the cord to pass from the uterus into the vagina. In the course of manipulation, this pressure is removed, the uterus returns to its normal shape, in this fashion drawing the contaminated cord back into the uterus. Thus Credé expression increases the number of infections. This passage of the cord may act within the membranes; however, with a lateral rupture of the membranes, the cord would come in direct contact with the uterus. The membranes themselves may form part of the swab which cultures bacteria from the vagina into the uterus (Figs. 5 and 6).

Early rupture of membranes leads to dry labor which means a long labor, especially a long second stage—so that dry labor increases the number of infections owing to the prolonged action of the fetus descending into the vagina and ascending into the uterus. With a dry labor, or early rupture of the membranes, there is also possible infection of the liquor amnii which acts as a culture medium and develops a more violent form of infection. In cases of placenta previa, the bleeding resulting in the last trimester, serves as an efficient plasmodium for developing virulent strains of bacteria in the vagina. This is a further aid in increasing the severity of the infection, when the bobbing of the fetus during labor draws the bacteria into the uterus.

So any body which passes through the infected vagina into the uterus, whether the cord, a part of the child, the hand or an instrument, will increase these possibilities for puerperal infection. Various operative procedures used in parturition; as forceps, version, craniectomy, and other methods, are performed within the amniotic sac, which protects the interior of the uterus. For this reason, these operations make the liability for infections (14) only three to five times that of normal labor. If a long duration of the second stage is added to the operative procedure, the morbidity will naturally be higher still, and yet higher if there is early rupture of membranes. However, none of these procedures carry with them the high risk of infection which does manual removal of retained secundines. This is the most dangerous operative procedure of obstetrics, for the reason that the hand or instrument passes through the bacteria covered vagina usually to the interior of the fundus of the uterus, thus implanting bacteria over the entire surface of the endometrium.

Prophylactic treatment (55) (67) (68) (69) (70) (71) (72) is necessary to prevent the appearance of

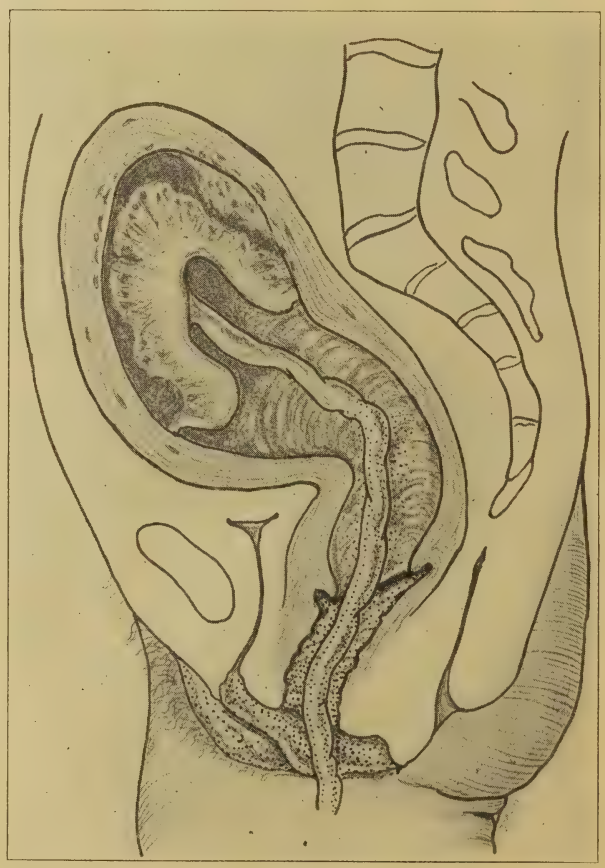

Fig. 6.

puerperal infection. Protection by prenatal care—cleanliness, increase of resistance by foods, liquids, rest, sleep, cheerfulness, out of door life, care of the bowels and kidneys—is of primary importance. Coitus should be forbidden in the last few weeks. At the time of delivery one should not interfere

except under the best of conditions and in case of necessity. Each case should receive the same care as a major operation.

Rectal examination should be made in preference to vaginal. Vaginal examinations are never made unless absolutely required. The body and clothing of the surgeon should be clean, the hands disinfected by scrubbing for ten minutes in soap and water and rinsing in alcohol for three minutes. The hands come in contact with the thighs, vulva, abdomen of the patient, so however sterile to begin with, they may not remain so. Gloves are a necessity: they protect the patient and the doctor. The number of lacerations is less with the use of gloves. Especially should long gloves be worn in performing version for this reason. The use of sterile gown, with cap and mask, is desirable.

The patient should be cleansed, shaved, clothed with sterile garments and placed in a clean bed. If, in using soap and water for perineal cleansing, some of this enters the vagina, it may carry with it infection to the uterus. For this reason, a sponge should cover the introitus during this cleansing. The vulva is painted with mercurochrome ten per cent. beginning with the labia minora, then the labia majora and then the perineum. An applicator paints this same substance over the vestibule and vaginal orifice. Numerous antiseptics have been used to attempt sterilization of the vagina. According to the statistics, some authors (46) (53) have presented some improvement in morbidity by their use, others (1) (71) (19) have noted an increase in infection after their use, while still others (1) (80) have noticed no change. The literature on this subject shows by no means that the vagina cannot be sterilized. If those drugs and methods used by the authors mentioned have not secured sterilization of the vagina, then drugs and methods must be found which will secure sterilization of the vagina. Apparently a douche in any form is of no value, or at least of very transitory value.

A diminution in the number of bacteria has been found (1) (81) for a period of eight to ten hours after administration. The drugs used in the douche have been lysol, lysoform, saline solution, lactic acid, bulgarian sour milk, bichloride of mercury. An antiseptic to sterilize the vagina apparently is more active when painted on the surface of the vagina. It should not injure the mucosa, and should interfere as little as possible with the vaginal secretions. Drugs which have been painted on the surface of the vagina are oxycyanate, sublimate, lysoform, potassium permanganate, boric acid, silver nitrate, *essingsaure tonerdelösung*, "bolus powder" and equal parts of crystal violet and brilliant (50). These drugs apparently secured some benefit in a series of forty-four cases, only two being infected. Mercurochrome in five per cent. to ten per cent. solutions may be used in the vagina and over the surface of the cervix without damage or injury to the mucosa. The use of iodine in these cases apparently causes swelling and dryness of the mucosa which the mercurochrome does not. Rucker (73) uses it preceding introduction of the bag or version. A series of cases at the close of this paper is reported in which mercurochrome has been used to sterilize the vagina.

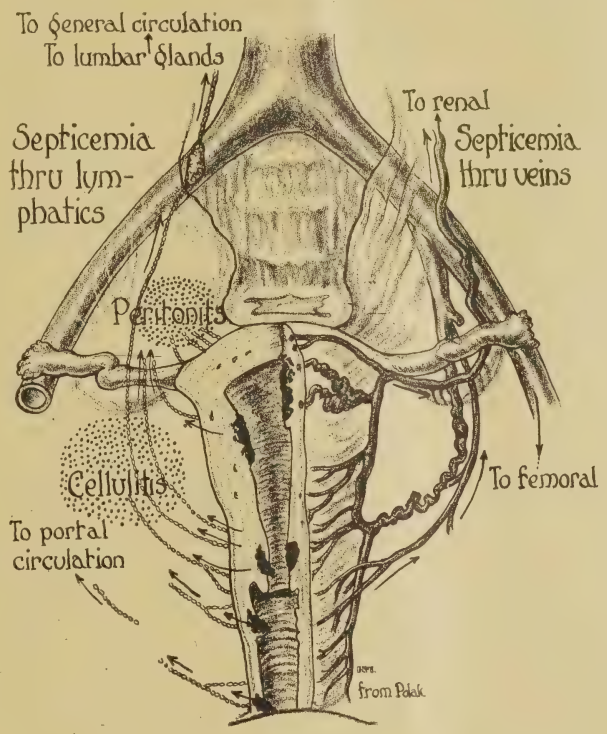

Fig. 7.

No interference is made in the conduct of the second stage of labor except in the case of necessity and under the best of conditions. Delivery is best performed without introducing instruments or hands; when hands or instruments are introduced, they should be covered with the solution of glycerin mercurochrome iodine which will be mentioned later. Lacerations of all sorts are avoided so far as possible, since these easily become infected by the vaginal flora and serve as avenues of dissemination of infection from that large portal of entry—the vagina itself, passing infections either through the blood stream or through the lymphatics. Pituitrin should be given only in multiparæ and after complete dilatation. Forceps are best applied to the head of the child (Fig. 7) carefully so that they come in the axis of the pelvis. If immediate delivery of a poorly dilated and poorly dilatable os is indicated it is better to use Duerrhsen incisions in the cervix and repair directly after the delivery. Fingers are better to dilate with than a metallic dilator. Preserve the bag of waters as long as possible. It is probably wiser not to repair cervical lacerations except to arrest hemorrhage, but all cervical incisions, perineal or vaginal lacerations or incisions should be repaired at the time of labor.

In the conduct of the third stage of labor, Ahland found his lowest morbidity when the third stage was one and a half hours long. If the placenta is separated from the uterus, it is all right to express it, but attempting to express a placenta still attached leads to a violent separation of the placenta, a tearing off and leaving of portions of the secundines, as well as tending to introduce infection as previously mentioned. If Credé's expression is done and parts of the secun-

dines remain within the uterus *do not attempt a manual removal—never invade the uterus* for smears, for placenta, secundines, or clots. The only indication for interference in the third stage is hemorrhage, and it is wiser to pack for this, if packing will check the hemorrhage, in conjunction with the use of blood coagulating drugs given intramuscularly, subcutaneously or intravenously aided by drugs which contract the uterus. After the third stage, with lacerations repaired, leave the parts alone. Watkins (58) has observed that cows have retained secundines until about the ninth day without fatal results. With careful preparation of the patient and careful conduct of labor, any fever which results from retained secundines is usually due to toxemia. It is wiser to attempt removal of retained débris if removal is necessary, when forced to do so by hemorrhage.

All cases of fever, postpartum, should be isolated. Most American obstetricians keep their patients in bed for nine to eleven days, but do not limit their motion. German obstetricians have their patients up in two to four days. The objections (77) (78) (79) to early sitting up are possibility of embolism and prolapse of the uterus. Embolism is very rare later than six to eight hours after delivery unless infection is present. For this reason, any patient who does not show fever (100.0°) may be permitted up in Fowler's position on the third day, sitting up in bed on the fourth day, in a chair on the fifth day and walking about on the sixth day. Sitting up early increases the tonicity of the uterus, aids drainage and prevents bleeding. Prolapse of the uterus, the second objection to this simple remedy for puerperal infections, may be prevented by the knee chest position. This is advised for five to ten minutes night and morning from the second to the sixth or eighth week inclusive, postpartum.

Following is the report of fifteen cases which have been prepared as follows: After shaving, washing and an enema, the labia, perineum and introitus are painted with ten per cent. mercurochrome. A large sterile speculum is then lubricated with sterile glycerine containing two per cent. mercurochrome and 0.6 per cent. of tincture of iodine (three and a half per cent.), inserted into the vagina and five c. c. of this same glycerine mercurochrome iodine solution are injected into the vault of the vagina. A pledget of sterile gauze is placed in the introitus to retain this solution in the vagina. It is observed that the vaginal mucosa is painted by the substance which has lubricated the leaves of the speculum. The first four cases were painted over the perineum, vulva, vagina and cervix with two per cent. mercurochrome, while the technic first described was finally considered best because in a glycerine vehicle, these antiseptic drugs will cleave to the vaginal wall and cover it with a sticky, viscid layer.

Two per cent. mercurochrome was thought advisable in the glycerine solution, because, if remaining in contact with the vaginal mucosa for a long period, it would be less irritating than a stronger solution. Six tenths per cent. of the tincture of iodine was added with the thought of increasing slightly the bactericidal properties of the mixture without making it more irritating. At the same time, if the entire solution were to be absorbed, it would be relatively nontoxic. The head coming down into such a vagina, will carry back into the uterus a coating of this antiseptic and paint the interior of the uterus with this substance rather than with infectious material.

My method of preparing this solution is as follows: Glycerini, 500; mercurochrome, 10; tr. iodini (three and a half per cent.), 3.

The tincture of iodine mixes readily with the sterile glycerine—making an extremely weak solution. The crystals of mercurochrome settle to the bottom of the bottle and inverting the container at intervals leads to its gradual solution in the course of three to five days. This solution has a beautiful reddish green hue, which stains anything it comes in contact with. Warming the mixture hastens its solution somewhat, but apparently does not injure its properties. It keeps well for six months and probably longer. Five cubic centimetres of this substance, the usual amount used in each case, contains four to five minims of tincture iodine—a standard dose, and the two per cent. mercurochrome, which is nontoxic.

Case I.—Patient, aged twenty-six, with family history of tuberculosis, had suffered from an abortion at three months, five years before consultation. She had been a telephone operator previous to marriage. Menstrual and past histories were without event. On physical examination there was present, constipation, hemorrhoids, caries of teeth, chronic tonsillitis, and pregnancy. Preparation with two per cent. mercurochrome twenty-four hours before final completion of labor, which was without mishap. Puerperium normal.

Case II.—Patient, aged twenty-five, with no important facts in the family, marital, social, occupational, or menstrual histories, had had measles, mumps, pertussis, bronchitis, and tonsillitis. On physical examination one found a primipara. She was delivered with low forceps, with a first degree laceration. Preparation with two per cent mercurochrome, twenty-four hours before the final termination of labor. Puerperium normal.

Case III.—A primipara, aged thirty-one, who had had measles, varicella, mumps, pertussis, without any evidence of disease in the family, marital, social, occupational, or menstrual histories. On physical examination, there was found a chronic cholecystitis, and thyroid enlargement, with pregnancy. She was delivered with low forceps, and suffered an episiotomy, and a second degree laceration of the perineum. Preparation with two per cent. mercurochrome, two hours and fifteen minutes before the final termination of labor. Puerperium normal.

Case IV.—A primipara, aged twenty-three, who has had bronchitis; without evidence of disease in the family, marital, social, occupational, or menstrual histories. On examination one found a mitral regurgitation and stenosis, a deviation of the nasal septum, with pregnancy. This patient had an early rupture of membranes, a dry labor, a version with forceps on the aftercoming head, a third degree laceration of the perineum, and retained secundines. Prepared with two per cent. mercurochrome nine hours before the final termination of labor. Puerperium febrile. Patient had a temperature of 100.4° for two days.

Case V.—A primipara, aged thirty-two, who had had measles, mumps, influenza, and sore throats, with no indications of disease in the family, marital, social, occupational, or menstrual histories. On

physical examination there was found, pyorrhea alveolaris, caries of teeth, constipation, acute bronchitis, and pregnancy. She was delivered with low forceps, with a second degree laceration of the perineum. Prepared with ten per cent. mercurochrome and glycerine mercurochrome iodine solution, four hours and fifteen minutes before final termination of labor. Puerperium normal.

CASE VI.—A primipara, aged thirty-two, single, with no evidence of disease in the family, social, occupational, or menstrual histories. On physical examination there was no evidence of disease. Patient was pregnant. She suffered from acute appendicitis, during pregnancy, which was relieved by operation. Preparation with ten per cent. mercurochrome, and glycerine mercurochrome iodine solution, twelve hours before the final completion of labor. Delivered spontaneously, with a deep second degree laceration. Puerperium normal.

(To be continued)

A New Method for the Early Diagnosis of Pregnancy and the Prognosis of Sex

RICHARD WEISS, M.D.
Berlin, Germany

Abderhalden (1) has shown that protective ferments appear in the animal organism following the parenteral administration of foreign substances, the ferments occurring in the serum and acting as solvents upon certain organic substrates, by inducing a catabolism to peptones. This catabolism and the enrichment of the serum with these peptones, is demonstrable qualitatively and quantitatively. This theory of Abderhalden lies at the basis of the serological diagnosis of pregnancy. However, the original test, which was associated with many difficulties and sources of error through the increased concentration of the serum produced by the catabolism with the aid of the dialyzation procedure and ninhydrin, did not affect the truth of the theory, but made the carrying out of the reaction useless for the general practitioner.

In more recent times a concise and accurate test was developed chiefly by Paul Hirsch of Jena, which has considerably widened the field of application for these serological investigations and which is so simple that it can now be carried out by the general practitioner. It requires no more technic and experience than a quantitative estimation of sugar. The chief requirement is a careful and clean technic according to the instructions and suitable apparatus.

This new test takes its origin from the fact that naphthochinon sulphate of sodium gives a very characteristic dark coloration with amino groups, the intensity of which depends upon the amount of the amino groups contained in the solution. If the serum alone is tested and compared with a test of the same serum that has come in contact with the substrate, we can recognize in a simple manner from the different intensity of the color in the two tests, whether decomposition products have developed or not. If the serum has undergone catabolism, the corresponding color is darker than that of the serum serving for comparison.

The technic of the reaction is as follows: With the patient fasting, blood is drawn through a Strauss needle from a vein of the arm into test tubes, and, preferably, two test tubes should be filled (nine c. c. of serum) and set aside to allow coagulation to take place. The serum is then poured off and also centrifugalized. Hemolytic serum should not be used, as this in itself gives positive results. The serum thus acquired is then diluted with 1:500 vuzin solution, so that there is an increased concentration of 1:10,000 (0.05 c. c. vuzin solution to each one c. c. of serum). The sterile tubes are then prepared according to the following scheme:

	P	T	O	Test
1.	Placenta substrate with 1 c.c. serum.	Testicular subtrate with 1 c.c. serum	Ovarian subtrate with 1 c.c. serum	
		with 1 c.c. serum	with 1 c.c. serum	Control
2.	1 c.c. serum	with 1 c.c. serum	with 1 c.c. serum	Control
3.	1 c.c. serum			

The tubes are closed with rubber stoppers that have been sterilized by boiling, carefully freed from any air bubbles that may be present, and placed in an incubator, where they are kept at 37.5 degrees C. for twenty-four hours. Up to this time the work must be done in absolutely sterile manner. If an incubator is not available, the test may be carried out in a moderately warm place, but the duration of the period of incubation must then be lengthened. Of course, the accuracy of the test will suffer somewhat. After twenty-four hours, deproteinization is done by removing the stoppers and adding the following amounts of the solutions mentioned to each tube, one after the other: seven c. c. of distilled water; one c. c. sodium tungstate solution; one c. c. two thirds normal sulphuric acid.

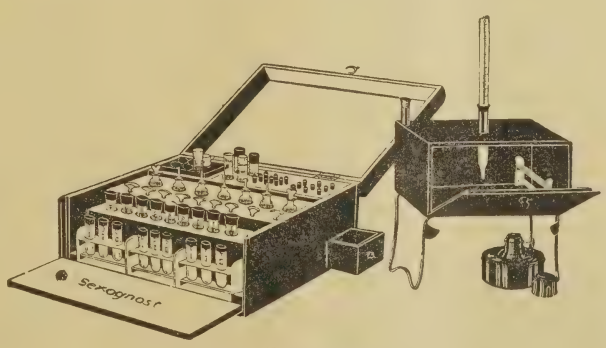

FIG.—The sexognost.

The tubes are again stoppered and well shaken. If a centrifuge is available, rapid centrifugalization can be done immediately. If not, the tubes are allowed to stand for one hour and then filtered through

a dry filter, and also into the tube that is marked similarly and standing behind, exactly up to a five c. c. mark. To this five c. c. of clear filtrate is added, first one drop of phenolphthalein solution and then soda solution, one drop at a time, until there just appears a persistent red coloration, which must be of the same intensity in all the tubes. When this is reached, the proper dye solution, namely, 1.5 c. c. of a freshly prepared 0.5 per cent. solution of naphthochinonsulphate of sodium, is added. After a thorough shaking this is placed in the dark for twenty-four hours, or at least over night. The dye solution should always be prepared fresh for each series of tests.

If one wishes to test with P (placental substrate for pregnancy) or with T and O (testicular substrate for male and ovarian substrate for female), one must use always the corresponding test tubes for control. If the serum is not sufficient for the nine tubes, one must be satisfied with one control for every substrate tube.

On the following day there is added to each tube one c. c. of the acetate mixture, and the tube is shaken; then one c. c. of the thiosulphate solution, and the tube is then filled to a fifteen c. c. mark with distilled water and again shaken. The excess of naphthochinonsulphate, not used up by the amino groups, is decolorized by the thiosulphate. The corresponding tubes are then set up alongside of one another in the comparator and their intensity of color is tested. If one of the test tubes (placental, testicular, or ovarian) is darker colored than the corresponding two or one control tubes containing no organic substrate, then catabolism has taken place, that is, the test is positive (P denotes pregnancy, T denotes a male, and O denotes a female fetus).

The following are the requisites for the proper carrying out of the test: 1. the blood should be taken in a fasting state; 2, the rejection of hemolytic serum; 3, sterility up to the time of deproteinization, and 4, accurate pipetting.

A specially constructed outfit, called the sexognost, is very useful. It consists of all the necessary apparatus, reagents and albumen powder, properly arranged, that are necessary for the test. The tubes are divided into three groups: Group 1 (marked P) for the demonstration of pregnancy; Group 2 (marked T) for the demonstration of a male fetus; Group 3 (marked O) for the demonstration of a female fetus. The first row contains the incubator tubes in three small metal stands, which can be placed into the incubator directly after their preparation. The second row contains the colorimetric tubes for comparison, in which the suitable test is carried out. The comparison of the various shades of color is made in the comparator, which is also furnished.

The Sedimentation Test in Gynecology*

IRVING SMILEY, M.D.
New York

The history of the sedimentation test dates back at least several hundred years. It was thought at the time that the test might prove of some value as an aid in the diagnosis of diseases, but, as such, led to little or no results and was abandoned. It was revived in 1917 by Fahraeus, a Swedish student, who employed it in the study of pregnancy. His conclusions were extremely interesting, and of sufficient importance to stimulate other investigators, especially among the Germans, to pursue the work further, resulting in the accumulation of an elaborate literature dealing with the rate of sedimentation in normal and abnormal conditions. This short résumé bears only upon conditions in the obstetrical and gynecological field of medicine, and an attempt will be made to show its application as an aid in diagnosis, differential diagnosis, prognosis, and other uses.

Several methods can be used to demonstrate this peculiar phenomenon of the blood in disease, but the Linzenmeier technic, because of its simplicity and accuracy, has superseded all other methods, and has been more or less universally adopted as the method of choice. The technic of the test is performed as follows: The tubes used are made of hard glass five mm. in diameter and 6.5 cm. in length, having a capacity of more than one c. c. They are marked at the one c. c. point and also at the eighteen mm. point. Lately the six, twelve and twenty-four mm. marks have also been added. These tubes together with a one c. c. hypodermic syringe with 0.1 c. c. divisions complete the outfit. It is important that both tubes and syringe be clear and dry. Two tenths c. c. of a five per cent. solution of sodium citrate solution is drawn into the syringe, to which is added 0.8 c. c. of blood drawn from one of the superficial veins of the arm, making the total contents of the syringe one c. c. The blood solution and the citrate solution are slowly mixed and then transferred to the tubes. The marginal level in the tube must be exactly at the one c. c. mark. The reactions are tested at room temperature since it has been found that in the incubator the rate of sedimentation was hastened, while the reverse took place when the specimen was placed in the refrigerator. The blood should be taken when the patient's stomach is empty, as acceleration of the rate may be caused by active digestion. The time is noted when the mixture is placed in the tube, and again when the line of demarcation between the erythrocytes and the plasma reaches the eighteen m.m. mark. A millimetre reading may also be taken at the end of the first hour. With blood therefor that sediments rapidly the results can be ascertained in a short time.

*From the Department of Gynecology, Bronx Hospital. Read before the Bronx Hospital Clinical Society, February, 1926. The North Bronx Medical Society, April, 1926.

Many theories have been advanced and many investigations have been undertaken to determine, if possible, the mechanism underlying the separation of erythrocytes from the plasma. Several factors undoubtedly enter into this phenomenon but definite information as to its exact causation has not as yet been determined. The reaction appears to be due to a chemical modification of the plasma, particularly in the relation of the colloids, an increase in the fibrinogin and serum globulin in relation to the serum albumins. The viscosity of the serum may be greatly altered by the formation of an extremely small amount of fibrin and fibrinogin. The greater tendency to agglutination of erythrocytes in albuminous solutions is a result of diminished negative electric charge of the erythrocytes themselves. This charge is highest in an albumin solution, lower in a globulin solution and lowest in a fibrinogin solution. Solutions of fibrinogin or globulin have a high viscosity, whereas solutions of albumin have a low viscosity. This may explain the relation between high viscosity of the plasma and the increase in the rate of sedimentation. Since the agglutinins carry positive electrical charges an increase will take up the negative charges of the erythrocytes, and the latter, no longer able to repel each other, are clumped together in massive rouleau formation. Another factor that may have had an important bearing on the reaction, may be the antagonism between the lipoid substances, cholesterin and lecithin. By adding cholesterin to the blood, the rate of sedimentation is extremely rapid, while the addition of lecithin causes considerable slowing. It would therefor appear that the changes occurring in the blood may be summed up as follows: In the plasma an increase in the fibrinogin and globulin and a relative decrease in albumin, hence an increase in the viscosity and diminution in the surface tension. In the erythrocytes a diminution in the negative electrical charge, with consequent changes in the surface tension (this depending also on the increased lipoid content of the plasma), and an increase in the viscosity of the erythrocytes.

A study of the literature of both Europe and America has revealed a remarkable uniformity of opinion as to the value of the test. Fahreus, Linzenmeier, Lehman, Geppert, and others in Europe, and Friedlander, Baer and Ries in this country, arrived at results and conclusions that are in fairly close agreement. They have established the test as one that is both reliable and trustworthy and as such can be of inestimable value in the study of the infections. In a very recent article by Cherry, however, the interpretation of the results in a given number of cases were in marked contrast to those of the others. His conclusions differed so radically that one is, at first glance, left in doubt as to the true value of the procedure, and it would appear that a thorough investigation would now have to be instituted in order to *evaluate* the true bearing of the test on the various factors pertaining to pathological conditions. The remarks under discussion in the following are based rather on the investigations of the European and American workers, and an attempt will be made to show wherein Cherry differs in his findings.

The separation of the erythrocytes from the plasma in healthy women should require from five to six hours; that is, in women in whom careful physical examination fails to disclose any pathological condition, the erythrocytes should reach the eighteen m.m. mark in the tube in about that time. It is rarely, if ever, necessary to be placed in a position whereby one is forced to wait that length of time in order to obtain the required information as to what is taking place in a given specimen of blood. Generally three hours are permitted for the lowest normal figures in healthy women, and a rate of sedimentation lower than this should be regarded as indicating an abnormal condition either apparent or concealed.

Much not only interesting and instructive but important as well can be learned from the study and observation of the test in diseased conditions. As an aid to a positive diagnosis the test is rather one of negative value, but in the fields of differential diagnosis and prognosis, and as an indicator for the proper and safe time to employ operative procedures the test is of extreme value, and can be considered reliable if properly interpreted. It should be emphasized that the test may be regarded as accurate only in connection with a careful accurate history, a thorough local and general physical examination and blood examinations. Anemias and cachexias do not permit normal values to supervene. A negative outcome of the test is particularly conclusive in showing that, at the time, no noteworthy inflammatory process is taking place in the body.

All inflammations, regardless of the etiology, cause a decrease in the time of sedimentation proportionate to the gravity of the infection, and the extension of the inflammatory products. Bacterial toxins, and products of protein catabolism accelerate the sedimentation time. Herein lies its great usefulness in gynecological conditions. The more acute the condition the more rapid the rate, less so in subacute, and slow in chronic forms. The presence or absence of an inflammatory process, either primary or secondary, in conjunction with a mass felt in the pelvis, the severity of the infection, the resistance of the patient, the presence or absence of latent infection, the fixed uterus with doubtful conditions present in the adnexæ, and many other factors pertinent to a clear, careful estimation of existing conditions, may be rightly judged and a fairly good understanding of what is going on in the individual patient be determined by means of the study of the test, which is repeated when found necessary.

The less virulent and numerous the bacteria, the less does the sedimentation vary from the normal, until finally it becomes normal, indicating thereby the disappearance of bacteria.

It becomes, thus, of great value in determining the period of safety for operative procedures indicating by its manifestations a safe and sane course to pursue. As a general rule and a safe one to follow it may be stated that any patient in whom the rate of sedimentation is sixty minutes or less is the subject of an acute infection, either local or general, severe enough in its nature definitely to contraindicate intraabdominal operative work, except in cases of ruptured ectopic pregnancy. A rate of one to two hours predicates either an infection that has shot its bolt, a less virulent infection, or a successful attempt on the part of the patient to overcome the condition. At this stage, while it may be reasonably safe, it is nevertheless often inadvisable to enter the abdomen since the pres-

ence of active bacteria is known to exist and a rejuvenation of the infection is not at all unlikely. When the sedimentation time is at the two hour period or over, safety in the employment of surgery is assured and, other factors being equal, the patient can be carried through with confidence.

At this point Cherry differs quite radically. In a series of cases totalling seventy-one in number, twenty-six patients were operated upon with removal of their pelvic lesions the sedimentation time being under thirty minutes. Another group of twenty-nine in whom the sedimentation time was thirty to sixty minutes were also operated upon. In sixteen patients the sedimentation time was sixty to 110 minutes. There was one death in the entire group. One is at a loss to explain the factors underlying the difference between the figures of Cherry and those of the other investigators. A further study of the conditions both external and internal that may have a bearing on the class of patient treated at the Harlem Hospital may be necessary to reconcile these conflicting opinions.

It might be advisable to take up individually the conditions one meets in the every day gynecological practice, correlate the facts influencing the rate of sedimentation and arrive thereby at conclusions that may serve in a practical fashion to assist in the treatment of diseases of the pelvis. The attention of the examining physician should be directed always along the lines of a thorough physical examination to eliminate as far as possible other foci of infection, other acute inflammatory conditions such as in the appendix, gallbladder, and other regions, which in themselves have a decided bearing upon the sedimentation time. Omitting, therefore, from here other fields of medicine, and devoting this short résumé to obstetrical and gynecological conditions, we may find the following:

As an aid in the early diagnosis of pregnancy the test has no value. At the twentieth week of gestation the rate begins to increase, and as the pregnancy advances the rapidity correspondingly increases. The most marked increase manifests itself in the last month when the eighteen mm. point may be reached within thirty minutes. Just before the onset of labor and during labor the rate will be found to be as low as fifteen minutes. It may therefore be possible, if occasion should arise, to predicate the termination of the period of pregnancy and the near approach of labor. An extremely lively rate of sedimentation would warn one that labor is imminent. For the first two or three days following labor the rate remains quite rapid, then rises slowly until the normal rate is reached. The failure of the rate to rise may be a premonitory sign of an impending puerperal infection in the course of development. A continued decrease in the time or the rate would indicate an infection of a severe grade with a prognosis more than likely doubtful. Conversely, a gradual slowing up of the rate means a rapid return to normal. The test, then, may be found to be extremely useful in estimating the prognosis of puerperal infections basing the knowledge of existing conditions relating to the infection on the rise or fall of the sedimentation time. The knowledge gained or to be gained by means of the test is more accurate, and can be recognized much earlier than any gained by observation of the temperature curve and study of the leucocytes.

A rapid sedimentation time in the course of an abortion should call for a careful investigation for either a concomitant infection somewhere in the genital tract, or possibly the onset of an infection incident to the abortion itself. The choice of treatment would depend a great deal upon the rate of sedimentation. A rapid decrease in the rate time would cause one to hesitate to employ intrauterine manipulations until such time is at hand when the rising rate indicates the road to safe and sane procedure. The same holds true in postabortal conditions. The choice of treatment, the reaction of the patient, the ultimate prognosis can be determined, and a fairer knowledge of the condition ascertained by the reading of the sedimentation time.

There is nothing to be expected from the test to guide one in the diagnosis of extrauterine pregnancy. When rupture takes place the rate time rapidly decreases and may often be as low as ten minutes, but the picture of the condition is so classical that the test becomes of little practical value. A slow acceleration of the rate in repeated tests may indicate, in conjunction with other objective findings, a tubal abortion, in which case the slow oozing of blood from the fimbriated end of the tube into the abdominal cavity may influence the rate of sedimentation. The test, however, is invaluable in the differential diagnosis between ectopic pregnancy and diseases of the adnexæ. A correct diagnosis is often beset with many difficulties, and errors are frequently made. Other factors being equal a rapid rate of sedimentation points rather to adnexal conditions. By exclusion a slow rate of sedimentation would tend to confirm a diagnosis of an extrauterine pregnancy.

In uncomplicated pelvic tumors such as myomas or ovarian cysts the rate of sedimentation remains normal. In the presence of acceleration there may be present an anemia from long continued even though slight hemorrhage, and the hemoglobin count may be of aid in determining this factor. Where the presence of extragenital infection can be ruled out a decided acceleration of the rate usually bears evidence that a softening or degeneration is taking place in the tumor, even before any change is noted in the temperature and leucocyte count. With a rapid increase in the rate time the importance of recognizing the cause is apparent. The test therefore becomes of considerable value in determining whether or not a tumor in the pelvis is undorgoing any change that may prove dangerous to the welfare of the patient. It happens occasionally that some difficulty arises in differentiating between pregnancy, fibroid, and ovarian cyst. Given a patient in whom a pelvic tumor is present a decreased rate time would give added evidence that pregnancy is the most logical diagnosis. This decrease in the rate would be gradual and would correspond to the growth of the tumor, while on the other hand a very rapid decrease in the rate time would point rather to a tumor with some complication present or impending. At the Harlem Hospital it was found that fibromyomas give about the same rate as pregnancies do. Considering the population of the Harlem Hospital, the prevalence of latent lues or tuberculous infections, which in themselves give a lively acceleration of the rate, Cherry's figures of twenty-five to seventy minutes for fibroids lend themselves to at least a reasonable doubt unless it be

assured that all extraneous infections can be definitely excluded.

The test finds its greatest usefulness in the evaluation of adnexal conditions. The presence of inflammatory processes, their nature and virulence, and the reaction of the patient to such infection can be determined with a fair degree of certainty by the careful consideration of the test. As an aid in differential diagnosis between adnexal diseases, ectopic gestations and other pelvic masses, the test can be very useful and may serve to render needed help in cases where the question often arises whether or not to operate. While the inadvisability of operating upon acute pelvic infections is not a new thought, many occasions nevertheless arise whereby operation becomes necessary. Our usual custom has been to await such time when the temperature has been normal for several days. We were even then unable to state definitely that a latent infection did not exist especially in those cases that had streptococci or staphylococci as the offending organisms. The sedimentation test may help considerably and a rate of two hours or over prior to operation will give positive proof that bacteria have disappeared, the infection at a standstill, and the patient is a safe operative risk.

In cases of cancer of the uterus the rapidity of the sedimentation constitutes a valuable addition to the diagnostic aids, especially for the recognition of doubtful cancers if it be combined in proper fashion with the blood count and a study of the color index. In cancer of the female genitalia there is constantly a deviation from the normal in the rate which, however, does not always correspond to the extent of the cancer, but is dependent upon the injury to the body as a whole. After radical operation the rate gradually returns to normal. In cases in which palpation indicates freedom from recurrence after operation it is justifiable to doubt the findings if the rate is greatly decreased and other processes which might be responsible for this change can be definitely excluded. The same holds true for cases where the patients have been radiated. Radiation in any form reacts unfavorably upon the test, and a rapid sedimentation is the usual picture following exposure. The rise in the rate is gradual and constant, and any decrease during the course of apparent physical improvement usually means a recurrence even though not discoverable at the time.

The sedimentation test should not replace careful observation of the temperature curve and repeated examination of the leucocytes. Both are valuable aids in studying the character of the conditions present. The test, however, serves the same purpose and has as an advantage the fact that it is often present before any change is noted in the count and gives better and earlier information between resistance on the one hand and virulence on the other. The test also allows of a better interpretation of the prognosis indicating a favorable or unfavorable outcome by its rise or fall, while the count and temperature curve may remain stationary or show little change, Cherry places more reliance in his operative work upon the count of the leucocytes. He divides his cases into two classes—those in which the leucocytosis is 16,000 or under (in which event he has no hesitancy in operating immediately), and those above 16,000 where operation is postponed to meet more favorable conditions. Nevertheless, Cherry, together with all other investigators, concedes that the test is a delicate one, and that it reacts much more quickly than does the increase in the number of leucocytes. When used in conjunction with the careful study of the leucocyte count and the temperature curve, a truer estimate of the nature of the condition, a clearer conception of the pathological condition present, a saner and wiser course to pursue, and a fairer knowledge of the ultimate prognosis will be the result.

Caffeine in the Breast Milk of Coffee and Tea Drinkers

ROBERT R. IRVIN, Ph.D.*

Pittsburgh, Pa.

The possibility of the excretion of caffeine into human milk from ingested coffee and tea is a question that has received little attention. From the viewpoint of the health of the child, it is obviously important to know whether or not this alkaloid does commonly occur in breast milk. P. B. Hawk (1) and A. L. Benedict (2) have suggested that the alkaloid may be present in the milk of tea and coffee drinking mothers, and thus exert a harmful effect upon the nursing infants. In 1908, C. B. Read (3) made an extensive bibliographic review of the literature on the occurrence of common drugs and chemicals in human milk, but, though a number of the more common alkaloids were discussed in his paper, no mention was made of caffeine. In a recent book (4) on nutrition problems of infancy and childhood by Stafford McLean and Helen L. Fales are also given a number of drugs, including some alkaloids, which have been found in breast milk, but caffeine is not included among those listed.

Because of the apparent lack of experimental data on the question, it seemed to be one worthy of investigation. It is evident, moreover, that the findings of such a study might readily have an important application in the matter of choice of diets for mothers with nursing infants. There is an old belief common among many women that tea drinking stimulates the flow of milk. It is conceivable that such a habit, when carried to excess, might cause the undesired result of drugging the infant.

*Industrial Fellow, Mellon Institute of Industrial Research, University of Pittsburgh, Pittsburgh, Pa.

In order to proceed with an investigation of this problem which I recently carried out, it was necessary first to establish a controlled source of supply of breast milk and to devise a method for the detection of small amounts of caffeine in milk. A suitable supply of human milk was arranged for through the cooperation of a local maternity hospital and later through the Public Health Nursing Association of Pittsburgh.[1] In the course of the development of a method for the detection of caffeine in milk, cow's milk, to which had been added small amounts of the pure alkaloid, was used for experimental study.

METHOD OF ANALYSIS

The preliminary work with cow's milk showed that small quantities of caffeine could be removed from it almost quantitatively and in a nearly pure condition by the following method: The milk was first dried in the presence of twenty per cent. of its weight of magnesium oxide. The resulting powdery mass was extracted with hot water and the aqueous filtrate in turn extracted with chloroform. Upon evaporation of the latter solvent, the caffeine was recovered almost quantitatively and with only a small amount of adhering impurities. For example, a pint of cow's milk to which had been added 0.0050 gram of caffeine, when analyzed by this method, yielded 0.0046 gram of caffeine after the removed alkaloid had been purified by the permanganate method.

For the detection of traces of caffeine in milk, it was learned that the best results were obtained when the dried chloroform extract was sublimed. This procedure was followed throughout in the analysis of human milk. It was found that caffeine could be thus recovered in a very fair state of purity, especially if sublimation was carried out in steps as was done in some of the later tests with human milk.

The formation of characteristic crystals with mercuric chloride was used as a confirmatory test for caffeine. According to this latter test, one drop of a 0.10 per cent. solution of caffeine will form characteristic crystals with the mercuric chloride reagent which can readily be recognized with the aid of low magnification.

EXAMINATION OF BREAST MILK OF COFFEE AND TEA DRINKERS

The breast milk analyzed for caffeine was obtained 1, from a selected group of patients in a maternity hospital, and 2, from an individual (colored, aged twenty-eight years; infant, aged five months) in a private home. From the hospital patients were secured 1,405 grams of milk and from the other source 3,340 grams. The women in the hospital used both tea and coffee. My analysis of these beverages showed that the average daily intake of caffeine was about two grains for each person. The subject outside the hospital drank only coffee, the amount taken varying from three cups a day at the beginning of the experiment to five cups during the last few weeks. The collection of milk from the person who drank only coffee extended over a period of ten weeks. The average cup of coffee as drunk by her contained 0.64 grain of caffeine and the maximum daily intake of the alkaloid was a little over three grains.

[1]This arrangement was made possible through the generous cooperation of Miss Helen A. Bigelow, Director of the Child Welfare Department of the Public Health Nursing Association of Pittsburgh.

From the milk of all the women mentioned above were obtained traces of a substance which had the crystalline form of caffeine and which, moreover, was soluble in both water and chloroform. It could be readily sublimed and deposited on a cold glass slide in the form of fine white needles. In only one instance, however, was a clear cut, positive test obtained with the mercuric chloride reagent. (This positive test was obtained with one lot of milk, about one third of the total, obtained from the subject who drank only coffee). In this case, and in a few other cases also, fractional sublimation was resorted to. It was discovered that cow's milk to which a trace of caffeine had been added would not respond to the mercuric chloride test unless the dried chloroform extract was very carefully sublimed in steps. The indefinite results obtained with this test in the case of other samples of human milk do not necessarily indicate the absence of caffeine, but rather show that traces of impurities were still present which formed insoluble compounds with mercuric chloride, thus making identification of the caffeinelike compound difficult.

Less than a milligram of the crystalline substance described above was obtained from all the human milk examined. Its purification and examination by ordinary chemical means were therefore practically impossible. That the substance was a derivative of caffeine is a possibility that should not be overlooked.

BREAST MILK OF NONCOFFEE DRINKERS

To preclude the possibility that the substance resembling caffeine found in the breast milk of coffee and tea drinkers might be a normal secretory product generally present in human milk, 1,103 grams of milk were obtained from a woman (colored, aged nineteen years; infant, aged two months) who, during the time of milk collection (about one month), used no coffee, tea or other alkaloid containing substance. The total absence of any crystalline substance resembling caffeine in this milk was proved by the method of analysis used in the preceding cases. Sublimation of the chloroform residue produced negative results. It will be recalled that crystals, capable of being sublimed, were always obtained from the milk of coffee or tea drinkers in previous experiments. It is of interest to note that cow's milk is also free from crystalline substance soluble in chloroform.

CONCLUSIONS

1. There has been constantly obtained from the breast milk of coffee and tea drinking mothers a substance possessing the characteristics of caffeine. In crystalline shape, solubility in water and chloroform, and in its capacity to be sublimed, this substance is highly suggestive of caffeine, or possibly a derivative thereof. Since it was found only in traces in human milk its absolute identification was extremely difficult.

2. The caffeinelike crystals just mentioned were found to be absent in the breast milk of a woman who drank no coffee, tea or other alkaloid containing substances.

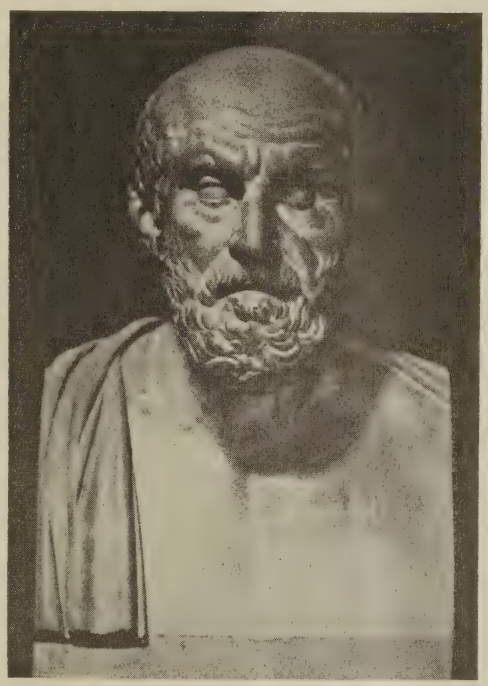
Historical Medicine

The Legacy of Greece to Galen

II. The Roots of Physiology and Etiology

JONATHAN WRIGHT, M.D.
Pleasantville, N. Y.

Although in the previous essay I have perhaps had more to say of Aristotle than of Plato, in reading Galen we soon perceive, as I have also said, he was inspired more by Plato than Aristotle. He places Plato, not Aristotle, side by side with Hippocrates and his instinct, for we scarcely attribute it to his careful study and comparison of his two great predecessors, is quite in accord with the measured judgment of even modern commentators on Aristotle. Ross, the latest editor and historiographer of Aristotle, remarks (1) in his introduction that his thought is colored far more than he knew by that of his predecessors, and above all by Plato, and the commentator says this having well in mind and specifically noting that Aristotle frequently speaks of himself as a Platonist. Gilbert Murray says Aristotle built an altar to Plato. For my purpose it is only necessary to remark that though Plato had a sort of atomic theory of his own in his triangles and their mathematic affinities, he never mentions the theory of Leucippus and Democritus and never mentions the name of the latter at all. Yet he frankly accepts the doctrine of the four elements, not only in the composition of the body, but of the soul. The latter had a large mixture of the divine, which also is indivisible and unchangeable, but in making the soul partake of corporeality and of mortality as well as immortality and incorporeality he recognized it must have an admixture of earth, air, water and fire. As to the mathematics that went with this, to us, strange and quite foreign conception, the figure four plays a large part in his arithmetic (2).



Term of Chrysippus. (Florence, Uffici)
(*After Hekler*)

From Heraclitus we judge he has his predilection for the element fire in the composition of the soul and it is fire among the ancient philosophers which more frequently than air has its suggestion of our late lamented ether. It is the lightest and most mobile. It plays the most prominent part in that ever changing aspect of things which so impressed Heraclitus and so impressed Plato that he made the geometric figure of the universe a sphere and circular motion the divine motion, so it could go on forever. The vortex of Democritus and Anaxagoras was a part of this same thought for it is only a circular motion can be eternal—eternally confined in a universe which had its limits for most of the ancient philosophy as it is beginning to have for modern astronomy, though they have extended the limits of space to figures which to the ordinary mortal are all but infinite. It was the fire penetrated everywhere and it was a circular motion, a spinning ball of a universe which kept going forever. Into how much of all this I may have gone elsewhere I can not be sure, but Robin (3) has much to say of this which is historically suggestive.

It was fire, it was the heat that we find in Aristotle as the motive force, or the agent of the motive force, in the functions of the animal economy and we must keep in mind that fire was an elementary matter or substance like earth and water and air and in most philosophies these were on occasion converted into one another. In Galen (4a) we get a glimpse how water was supposed to be transformed into another socalled element. It became thick and compressed and settled down into solid earth. "It was capable of it and of rising up as frothy air"—at least so I would translate it and the Latin rendering of Kühn does not forbid. How near this was to the thought of the Nature philosophers or whether there was not some further explanation of the process I do not know, but Galen seems to think that sufficient and this he thinks was their conception of the manner of the transformation of other forms into a single elementary matter, which is really the point of interest for us gazing at a distant star and saying there matter is being transformed into heat or energy. That is fire. Then Galen goes on to repeat this in just about the same terms reversed for fire into air and air into water and water settles down into earth. We easily conjecture the mist rising from the sea and the earth emerging from it out of the silt deposit of rivers were the natural phenomena out of which this naïve conception grew, but the point that bids us halt is the point we have reached where matter is transformed into energy. It is fire or Aristotle's internal heat which sets the dervish whirling just as it sets worlds whirling, but we must beware of reading something into the ancient mind which was never

there. We must remember, too, it was Galen's nature to cast ridicule on an argument rather than to seek out the rational basis or the basis of fact on which it rested. He had no conception of the mental dissection that seeks to lay bare the origin of a thought as he laid bare the origin of a monkey's spinal nerve. Bellowing at an opponent was better. Otherwise he would not have exclaimed: "This is the extraordinary trend of their arguments." William James was much amused at the bellowing in the German meetings of science, but he might have found it nearer home, not in the pulpits alone of science but in the conventicles where science is taught from platforms. Seeking truth as Socrates did was a matter of groping, retreating and advancing, always in doubt, never oracular, backing out of one blind alley and skirting another. The smooth pearls of wisdom and the oriental flattery of the modern platform orator of science have no more place in the search of truth than the periods of the eloquence of Gorgias had, in Socrates's view, but bellowing was Galen's way.

It may be thought I have picked up the trail of medical thought as to the roots of disease at some distance from medicine itself. Going back therefore to Galen busy with advanced physics and the borders of metaphysics, we see him at least penetrated by the thought that no one can understand the roots of medicine without dealing with the former.

Although Aristotle is said, erroneously I think, to have been a physician himself, he was undoubtedly the son of a physician. He was a great biologist, the greatest of all of them, modern or ancient, and though his reference to the pathology of disease is negligible, his contributions to anatomy and physiology was so great it seems at first sight singular that Galen, who was not a success as a metaphysician or a theologian, should have placed Plato instead of Aristotle by the side of Hippocrates in the title of his commentaries on the dogmas of the philosophers. It may, as has been suggested for his interest in making *The Nature of Man* a genuine book of the great Hippocrates, have been because in the *Timaeus* Plato makes the elements precisely four in number and the attribute of matter four, the humors four, though on these he lays less stress. But it was these that attracted Galen, obsessed with his pernicious humoral doctrines. It was from the spurious Hippocrates and from Plato, Galen drew these theories which became so hidebound under his hand. Plato was very much more in line with these than Aristotle, but Galen apparently would have nothing to do with Plato's triangles. They were set vibrating by vibrating particles outside of the body and they may have other attributes attractive historically to the modern physicist. There the earth and air particles are set whirling and while they are in a whirl they interpenetrate with others. This sort of movement communicated to the triangular particles within the animal body through the sense organs, of taste specifically, by the path of bloodvessels to the heart or perhaps the brain, give rise to the sensations of pleasure or pain in the centres of the soul or consciousness. This is, as I take it, the doctrine of sense impressions in the *Timaeus* (64-70), but it appears so interlarded with other physiological and psychical matter, as we now apportion it, that it is difficult to extract it from its environment. It was not in accord with the view of Aristotle and Galen and it is not the part of the Platonic theories to which the latter lends his approval, but we can lend a more sympathetic ear to it. Before Plato Empedocles made minute particles play their part in the sense of sight and their beating on the retina is one of the forms of modern views. Plato applied it to the gustatory sense. As to these views, Beare has left others very little to say and they can be better pursued in his masterly book (5).

Starting with the very earliest of man's ideas as to the soul, merged with the idea of life whose seat was in the blood, we find the germs of the theory of the pneuma. It was well to the front before Erasistratus gave it prominence through the observation of the change wrought by the oxygenation of the blood in the lungs. The pneuma or the oxygen traveling everywhere in the bloodvessels of the arterial system and animating and refreshing and nourishing the tissues it would have been strange indeed if its vehicle, the blood, had not itself become the seat of the soul and the mysterious change of its color had not become the link which bound man to the Infinite, but it is astounding to us that Erasistratus thought this activating principle in it traveled in the arteries alone. It is pneuma then, which has something of fire and the ether in its conception that is the ultimate source of the movements of the body. In this dilemma Galen says (4b) even Diogenes Apollonius, the champion of air as the monistic element forgets himself and agrees with Empedocles and Kritias that the blood is the source of life. They were both of them Silicians, to whom Plato owed so much in philosophy and religion and from whom he suffered so much in politics. They, Galen declares, believed the blood is the soul, while Cleanthes and Chrysippus and Zeno were of the opinion it nourished the soul. The latter is the natural development of Platonic philosophic thought. We see therefore these two fundamental theories, each having its origin in primitive thought are the roots of ancient medical physiology which intertwine not alone at their origin in the mind of primitive man, but in the minds of Greek thinkers, who accumulated a legacy for Galen.

Very much the largest amount of the talk about the pneuma and the soul in the medicine before Galen was in the shelter of the ignorance of the functions of the brain and of the lack of differentiation between the nerves and the fibrous structures of the body. Herophilus and Eudemus (4c) first, long after Aristotle, gave a full exposition of the true nature of these, but we may find even Aristotle saying there were those who believe the brain was the source of life and movement and some that it is the heart. He partook of the latter opinion and we may trace this thought to that of the pneuma in the blood animating and nourishing the body. It dominated thought for six or seven hundred years after Alcmaeon is said to have traced the cerebral nerves to their origin, during which time Plato advanced far enough to make the brain the seat of the noblest division of his tripartite soul. In the *Sacred Disease* we find the function of the brain recognized, but in the more genuine and earlier books of the Hippocratic Corpus that is not the case, so far as I remember. Until the nerves were differentiated and their function demonstrated the brain theory must have remained in the greatest obscurity and doubt and disbelief.

It is not clear at all how much research work was done before Galen on the nerves and bloodvessels and especially as to the physiologyy of the latter. It is evident a great deal had been done before him at Alexandria as to their anatomy, but how much had been done to bring the physiology into some kind of harmony with it is far from clear. Aretaeus so well understood it he made a correct diagnosis of the lesion in cerebral apoplexy. Archigines lived before Galen, probably in the reign of Trajan. His pneumatic theories Galen attacked, but Aretaeus shared them fully and him Galen does not mention nor does Aretaeus mention Galen, although they were evidently contemporaries and both Asiatics by birth. Aretaeus was the Cappadocian and Galen was born in the neighboring province of Bithynia, though the maps leave us in doubt as to their contiguity. Galen traveled much in the eastern Mediterranean, even when he resided and practised at Rome. It is difficult to believe they did not know of one another. It is still more astonishing there is hardly any contemporary mention of Galen. There is a doubtful one referring to him as the Mule Head of debate by Apollonius Aphrodisiensis, I believe, and a distinctly eulogistic mention of him by Athenaeus of Naucratis (6), but it is not certain when the latter lived. At least it was long before Oribasius, who does not especially distinguish him in his collection made for the Emperor Julian. However, he is not backward in blowing his own trumpet, and we know very specifically about him from his own words. If all he tells of his own work is true, if none had before him done what he did to elucidate the functions of the nerves and bloodvessels of the body he was by far the greatest experimentalist and medical researcher who ever lived. He did enough forever to banish the misty talk about the soul and the pneuma being the cause of the body movement, but we will go far astray in the history of thought unless we recognize the grain of truth in regard to the pneuma and acknowledge the mysterious link materialism has with the discourse of Plato on the soul.

I have heretofore been interested here to show Galen's reaction to the dogmas of Plato and Aristotle as to the elementary philosophy which was the foundation of his medical theories. He did battle with those of Aristotle, he evaded those of Plato as much as possible where his materialism compelled him to do so, but in his worship of Hippocrates he seems on occasion to have supplied him with ideas he apparently never had. Aristotle, but especially the Stoics and Peripatetics (4d) and especially among them, Chrysippus, are usually in the wrong and Plato usually in the right and Hippocrates always so. According to Hippocrates the heart is the origin of the pneuma and the source of the blood and "although Hippocrates talks like a physician and Plato like a philosopher, they are in virtual agreement"—about something which we can only look on now as mere verbiage, but by which Galen, though having his doubts, was greatly influenced. He did not in our view at all act up to his principles. "A reasonable argument is one based on facts," but even we, matter of fact generation as we profess to be, have to admit a good deal of unreasonable argument is based on it too. Emotion stirs the heart and bilious people are apt to be hypochondriacal and irritable, but generosity dwells in the heart and evil dwells in the liver. That the soul dwells in the choroid plexus and the ventricles of the brain may be talking like an ancient philosopher whose thoughts we can perhaps trace, but that is not the way the modern philosopher bases a reasonable argument on fact. Galen was disposed to admit all these arguments for the tripartite soul when he talks like a physician, but in various other passages he is censorious of the ways both philosophers and physicians use words.

Chrysippus is only following Aristotle in the ridiculous account Galen gives of him. Aristotle, too, is much concerned about the loose application of words. The trouble was not so much with this or rather this was apparently secondary to the loose thinking and that Aristotle more than any man in the world did most in an attempt to correct and he was born when in this respect he was needed the most, but his efforts were not crowned with success, so far as we can judge from Galen's accounts of his followers. It was unfortunate for straight thinking and acute analyses that Aristotle came at the end of the glory of Athens. His own language has been the despair of a thousand commentators and translators, yet through it all shines the intellect of the man who scarcely less than his great master bequeathed to Galen his legacy, but great minds are impotent in the face of cosmic change.

Dr. Dubuisson and the Conspiracy of General Malet.—With the aid of documents for the most part unedited, Commandant Sérignan, formerly professor of history at Saint-Cyr, has brought to life the conspiracy organized and carried out in 1812 by General Malet against Napoleon.

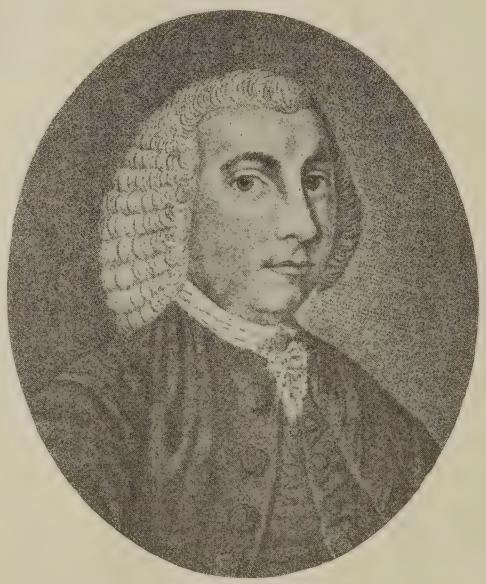
This prisoner of state, incarcerated for years with no communication from outside and without accomplices, escaping from jail by a window, essaying to destroy the power, then at its height, of Napoleon, the power of a prince armed with large and a formidable police force, and succeeding for the moment in his daredevil enterprise; such is in a few words the most extraordinary attempt at insurrection, and the most audacious, that history has ever known. It was on the night of October 23-24, 1812, that General Malet made his tentative *coup d'état.* Incarcerated because of his republican principles, Malet obtained a transfer for himself from Sainte-Pélagie to the sanitarium of Dr. Dubuisson, which he entered on January 10, 1810. The surveillance here was practically nil and Malet was able to prepare his attempt at his leisure.—*Æsculape.*

Contributors to the Science of Medicine

Tobias Smollett

As a contributor to the science of medicine Tobias Smollett should find no place here, but as a man who illumined the name of doctor by his great literary gifts he deserves a place in a list of great men of any age. The career of Rabelais has been given, so why not that of Smollett.

He was born near Cameron on the banks of the river Leven in Scotland, in 1720. He received a good classical education and was taught medicine and surgery in the manner customary at the time. After qualifying he became a ship's surgeon, or surgeon's mate, in the British Navy, and was present at the siege of Carthagena. In his novel, *Roderick Random,* he has given a stirring account of this expedition. In 1756 he is supposed to have been the editor of *A Compendium of Authentic Voyages,* published in seven volumes, among which is contained a short narrative of the expedition to Carthagena in 1741, which is splenetic and spicy as most of his writings are.



TOBIAS SMOLLETT, M.D.

He did not stay at sea for long, and no doubt wrote many things before he became known as a literary star. In 1746 he published *A Satire in Two Parts.* At eighteen he had written a tragedy, *The Regicide,* founded on the story of the assassination of James I of Scotland. This he published by subscription in 1749 with a preface in which he inveighs bitterly against false patrons, and the duplicity of theatrical managers. Iu 1757 his comedy of the *Reprisals,* an afterpiece of two acts, which he had written some years before, was performed in the Drury Lane Theatre. He had also prepared an opera entitled *Alceste,* which has never been put on the stage nor printed. Handel composed the music for it but finding that no use was to be made of it afterwards adapted it to Dryden's Lesser Ode for St. Cecilia's Day.

So much for his dramatic works which brought him little fame. It is his works of fiction on which his fame rests and it is now generally acknowledged that he was a very great novelist, one of the greatest in his own particular line. In 1745 he published *Roderick Random* and leapt at once into fame. It is one of the great novels of the English language. In 1751 *Peregrine Pickle* appeared, a novel of lesser calibre, but one well worthy of Smollett's genius. This novel is marked by two striking episodes. The first tells of the adventures of a lady of rank whose name was well known. The other describes an entertainment given by a republican doctor, after the manner of the ancients. The doctor caricatured was supposed to be Dr. Mark Akenside of Newcastle, who made a considerable reputation as a poet. Profound learning and genuine humor predominate in this episode. It may be said that Smollett was learned and endowed with humor which was frequently of a sarcastic, sometimes of a sardonic, nature. In 1754 was published *Ferdinand Count Fathom;* in 1762 *Sir Launcelot Greaves,* and in 1771 *Humphry Clinker.*

Before he took a house at Chelsea, he attempted to practise as a physician at Bath, and with this end in view published a treatise upon the waters of Bath. However, as he did not succeed in practice he abandoned once and for all the medical profession and devoted himself to literature as a means of livelihood. He translated *Gil Blas* and *Don Quixote,* the latter was published in 1755, and after his death a translation of *Telemachus* by him appeared. His name also is appended to a translation of the prose works of Voltaire. In 1757 he published a *History of England* and was employed during the last years of his life in preparing a new edition of *The Ancient and Modern Universal History.* He wrote some part of this himself, the histories of France, Italy and Germany, in particular.

In 1755 he set on foot the *Critical Review* and continued as manager of it until he went abroad for the first time in 1763. This publication involved him in several controversies and law suits, the most important of which was occasioned by his remarks on a pamphlet of Admiral Knowles, the commander of the ill fated expedition to Rochfort, in defense of his conduct of it. The admiral prosecuted Smollet for libel which ended in his being fined one hundred pounds and condemned to three months' imprisonment. As the author of the *Review,* he was frequently censured on account of articles which appeared therein and in which he had no concern.

Smollett also supported Lord Bute, who was the court favorite of the day and who was supposed to have the reins of government in his hands. Smollett published *The Briton* in support of one of the weakest men who ever received the favor of a king and also wrote other pieces in support of the same cause. By the irony of fate he received no profit from these writings. However, Smollett was not the only great man who had to prostitute his genius to mean aims in those times. An author without money was compelled to seek the patronage of a titled mediocrity

who basked in the reflected glory. Moreover, like Samuel Johnson, Smollett, of an independent proud spirit, was ill fitted to lick the shoes of such as the Marquis of Bute and accordingly he was in hot water continually and never succeeded in a material way. His pecuniary and other difficulties reacted on him and rendered a somewhat spiteful wit and humor more biting.

As said before, he went abroad in 1763 as his health was bad, and resided for two years in France and Italy. He published an account of his sojourn in these countries in 1766, in them displaying to the full extent his splenetic humor. However, as his health continued to fail after his return to England, he went back to Italy where he died on October 21, 1771.

Smollett was one of those learned men of genuis, whom Pierius Valerianus would have included in his book *De Infelicitate Literatorum*. At his best he was a writer of the highest genius and although neglected during his life has been so acclaimed by posterity. His remarkable powers and attainments never gained him higher patrons than booksellers, with the exception of the despicable Marquis of Bute. In order to live he had to waste his talents on hack writing. One of his biographers attributes his lack of success to a certain "loftiness and elevation of sentiment and character which he possessed" and, as the biographer justly adds, are but poor qualifications for "currying favor with those who are able to confer favors." He met many mortifications and disappointments. He said in a letter to his friend, David Garrick, the great actor, "I am old enough to have seen and observed that we are all playthings of fortune, and that it depends upon something as insignificant and precarious as the tossing up of a halfpenny, whether a man rises to affluence and honors, or continues to his dying day struggling with the difficulties and disgraces of life."

With these difficulties and disgraces he had to struggle throughout his life. Smollett is now regarded as one of the brightest lights of English fiction. *Roderick Random* is the finest novel of its kind written and should be read by medical men if only for the graphic pen pictures of the life of a surgeon of a man of war of that period. Smollett by his genius added lustre to the name of doctor and in company with that even greater genius. Rabelais who also was a physician and whose career has been commemorated in these pages, his fame will endure.

Graduate Study in New York in 1876

Some interesting items related to graduate study in medicine in New York City about the year 1876 have been very kindly contributed by Dr. Howard Jones, of Circleville, Ohio, after reading the article on the Early Years of the New York Post Graduate School and Hospital, by Dr. Henry Dwight Chapin, which appeared in this Journal.

Dr. Jones writes that he was graduated from the Ohio Medical College in the spring of 1876, then went to New York and matriculated in the College of Physicians and Surgeons and the University Medical School. His diploma gave him matriculation at a nominal cost in both these schools, and he was admitted to the lectures by a ticket, which he has preserved. Here the student had the choice of instruction under such teachers as he chose. Before the autumn of 1876 had passed, private classes were organized under an agreement between the same men who later organized the Post Graduate School, and it was then discussed as one of the future possibilities of medical instruction in New York City. These men issued tickets to their clinical lectures, which were then given, according to Dr. Janes, at the Demilt Dispensary or at the private offices of the various physicians. This lecture course continued for a certain number of weeks throughout the winter, at a cost to each student of about $15 to $20 a week.

Dr. Jones tells us that quite a number of western boys with degrees availed themselves of these courses, as many as fifteen when he was in New York. Among the instructors were Dr. D. B. St. John Roosa, Dr. L. Duncan Bulkley, Dr. Hanks, Dr. Thomas E. Satterthwaite in microscopical pathology, and Dr. Louis Sayer in plaster work for orthopedic cases. These men all issued tickets admitting the bearer to their lectures. Dr. Satterthwaite used his personal card instead of a printed ticket. Dr. Jones has kept these tickets, signed by the lecturers and

Editorial Articles

LAWS; HUMAN AND DIVINE

There are laws of health, but they are not human laws nor are we always sure that we know these laws when we think we do. Human laws of health turn out to be very troublesome when it is found that they do not correspond with the real thing. We all mouth these laws occasionally as suits our purpose, but it is those which get themselves written down in the statutes that prove most disastrous, since they cannot be repealed without considerable cranking of the cumbersome machinery of legislation.

Just at present it is the human law on ventilation, especially ventilation of school buildings, which is proving troublesome. Within a couple of decades twenty or more state legislatures or state departments of education have ruled that thirty cubic feet of air must be delivered to each school child ever minute, for it was the teaching of the science of the time in which these laws were formulated that such were the needs for health. A newer science which knows not the god (or devil) of carbon dioxide and other deleterious agencies in the air, lays down the new law that forced ventilation is not needed nor so good as the opening of windows over radiators. If this is Nature's law of healthy air for schools it is now impossible for superintendents of schools in these twenty states to fulfil this law, since they are compelled by the existing human ordinances to insert machinery for producing forced draft.

If the new method of ventilation is sufficient, there is a saving in fuel of some thirty per cent. and there is also a considerable saving in building costs if the forced draft machinery is omitted in the construction. It would seem simple enough to have the old human laws revised to conform to these new human laws, but, unfortunately, the former have become intrenched in human self interest involved in the making of various patent systems for the delivery of the thirty feet of fresh air per minute. It will be much more difficult to secure the repeal of these ventilation laws than it was to secure their passage, even though the former would prove a matter of much public economy.

The moral would seem to be to get along with as few and as general human laws as possible in order that we may readily adjust to the better knowledge we may possibly and probably acquire of Nature's requirements.

While it would seem that, aside from comfort (which, according to recent studies, is about all that is needed in ventilation), the air of a room should be kept as pure as possible, so far as the machinery of forced draft is concerned it seldom works as it is supposed to work and the human law is not fulfilled. Moreover, the machinery of forced draft is rarely operated out of the season for heating. In other words, it is noneffective save in those months when the rooms must be heated. So far as illness of school children is concerned these are by far the healthiest months of the year. In the experiments of the New York State Commission on Ventilation, carried on over eight weeks in the late winter months, there was an average of eighteen per cent. more absence due to respiratory illness and seventy per cent. more illness among those in attendance in the fan ventilated schools than in those with open windows only.

After all, open window ventilation would seem to be Nature's ventilation, for it is only man who huddles together indoors in large groups, only man who heats his houses, only man who has invented machinery for forced draft, and only man who formulates laws of health.

TRUSTY PHYSICIANS

"I would like to have an annual physical examination if I only could trust the physician, but, from my experience, they don't know how to examine." Such is the delivery of a very intelligent layman with regard to examinations "on your birthday." In this man's estimate thoroughness and knowledge are expected from the physician and he is suspicious of one who does not exhibit them, and, unfortunately, he finds the knowing and thorough doctor a scarce article.

It is not more than we would expect, however, since it has not been very long since the whole teaching of physical examination was the exploration of organs (heart and lungs) of which perhaps least can be learned, save where they are damaged beyond any possibility of repair, while an investigation into habits of living is well nigh foreign to medical reckoning.

If the physician would only use his eyes and his ears and his knowledge, he could usually be trusted. A child not recovered from measles manifests a fever. The parent is told by the family doctor that the child has "liver trouble caused by a poisoned lollypop," although this physician is perfectly aware that hundreds of other children have been sucking the same lollypops without "liver trouble" or fever. It was so much easier to give this preposterous but

untrustworthy explanation than to examine the chest where the trouble was later found. The questions asked by parents and friends are often troublesome to answer, but they deserve a trustworthy answer founded on the best knowledge obtainable.

If the nature of the medical student has not materially changed of late years, and it probably has not, a large percentage of it is hoping to excel in the daring art of surgery, or, failing that, to fall into the easy task of writing prescriptions. We wonder how many will be fitted by inclination for making valuable health examinations and whether it may not be well to train in our medical schools a select group of students along these special lines. At any rate, those who have the courage to plan to be general practitioners deserve to have special training along such lines, as fundamental to their future work, since the public is being educated to desire annual examinations.

It would not be an easy specialty, this of the annual examination, and, therefore, should encourage the student, for it would enlist all the knowledge and skill now procurable from the medical curriculum and experience. Our tests of organic condition should be of the most refined order, for they are gross enough at best. Tests of hygienic practice need not be so difficult to study, but they, too, need detailed study. The matter of diet, which comes first in importance, cannot be settled by inquiring as to how many meals a man eats. Indeed, the physician who can be "trusted" fully to examine and advise in hygiene must be not only well schooled but wise, for our ever fickle science must be well larded with common sense if we are not to prove blind (or very nearsighted) leaders of those who suffer from defective vision in this matter of healthy living.

RADIUM IN THE TREATMENT OF NONMALIGNANT DISEASES

Radium and x rays have had a fair amount of success in the treatment of malignant diseases, but the histological effects of radium require a great deal more close study and probably, until more coordinated efforts have been established successfully to bring about a standard technic, it would be unwise to speak in any way dogmatically on the subject. Ignorance as to the rationale of radium treatment needs to be more fully removed. However, progress is being made in this direction and it is to be hoped that scientific investigation on a much wider scale than is now the case may in time clear up most of the obscure points and teach with more or less precision the exact value of radium in the treatment of malignant disease.

In the radium treatment of certain nonmalignant diseases and conditions, reports are encouraging. For instance, the latest report of the British Medical Research Council on the medical uses of radium, being a summary of reports from research centres in Great Britain and Ireland for 1924, affords ground for hope that with the gathering of further knowledge radium may be found to be a factor of the first importance in the treatment of certain malignant and nonmalignant diseases and conditions.

The report in question in discussing the radium treatment of nonmalignant diseases is concerned for the most part with gynecological conditions and diseases of the blood.

So far as gynecological conditions are concerned, from the data contained in the reports the committee is convinced that radium is completely efficient in creating an artificial menopause or cutting short a prolonged and abnormal climacteric. The minimum dose which has produced the desired result would seem to be about thirty-five milligrams of radium element used for twenty-four hours, but the usual dose, and more certain in its results, is seventy milligrams of radium element in the body of the uterus for twenty-four hours. It is noted with interest by the committee that at one hospital it is used as a routine method in such cases. They do not feel, therefore, that there is any need for further research where an absolute cessation of menstruation is aimed at. They feel that more research work might profitably be carried out on patients between the ages of twenty-five and forty suffering from intractable hemorrhage, and in which it is desirable to control the hemorrhage by small doses without causing a premature menopause. The reports on fibroids suggest that for the treatment of small fibroids giving rise to menorrhagia, radium treatment is of great value, but generally causes an artificial menopause, and in a few cases the fibroids diminish in size.

Finally it is suggested that more work might be carried out on patients suffering from chronic cervicitis to find out whether it is possible to destroy the mucous glands of the cervix without at the same time destroying the ovaries and producing an artificial climacteric.

With regard to the use of radium in the treatment of blood diseases it is reported from the Royal Infirmary of Aberdeen that in six out of seven cases of myeloid leucemia treated by the external application of radium either to the spleen or to the long bones, there was considerable improvement in the condition. In some cases a quick and very pronounced fall in the numbers of circulating leucocytes occurred. In others this diminution was spread over a period of many months. Though these patients have undoubtedly been greatly benefited by the radia-

tion treatment, no essentially new facts have been brought to light by these therapeutic measures.

On the whole, then, it may be said again that the report is encouraging but that there is much to learn concerning radium before its value as a therapeutic agent can be fully assessed, and particularly should its histological effects be studied with the utmost attention.

THE BLOOD, LYMPH, AND INTERSTITIAL FLUIDS IN CANCER

At its onset, cancer—a local process—exercises no influence over the figured elements of the blood, and it is only when the neoplasm has undergone necrosis or infection that the blood formula becomes variously changed according to these complications. The influence of cancer is manifest in the blood serum at the beginning of the precancerous phase, as has been recently experimentally proved. At the onset of the process both physical and chemical procedures detect changes in the serum. Electrophoresis gives a greater precipitate than normal at the positive electrode; a solution of tannin gives rise to a larger precipitate in the serum of a cancerized animal than in that of the control, the colorimetric procedure with tyrosinase paracresol reveals abnormal quantities of aminoacids and amines.

At the onset or at the phase of full development the serum of cancer subjects gives reactions similar to the preceding ones, but varying in intensity. The degree of intensity varies not only with the phase of evolution, but with the nature of the neoplasm and therapeutic measures employed.

Neoplasms with a slow evolution give mildly positive reactions, while those with rapid evolution and untreated give strongly positive reactions. Reactions intermediary to these are noted in improved cancer cases. When the neoplasm has to be thoroughly removed surgically the reactions become negative in from one to four weeks and in subjects treated only with intravenous injections of autoserum charged with radium emanations, negative reactions ensue in from one to two weeks after treatment.

Chemical analysis of the serum of cancerous subjects has revealed certain data of frequency that are worthy of attention. There is an increase of the globulins and aminoacids of potassium in rapidly growing tumors, as well as calcium in slowly growing neoplasms.

As yet no specific substances have been detected in the serum of cancerous subjects, only differences in quantity and physicochemical changes of substances normally present. In all these researches one is dealing with general biological facts observed in all cases of intense cell destruction.

AN AFRICAN EXPEDITION

A Harvard Expedition has just started for Africa, headed by Dr. Richard P. Strong, professor of tropical medicine, Harvard University, with the following staff: Dr. George C. Shattuck, assistant professor of tropical medicine; Dr. Joseph Bequaert, assistant professor of entomology; Dr. Glover Allen, lecturer on zoology in the Museum of Comparative Zoology; Dr. Max Theiler, instructor in tropical medicine; Dr. David H. Linder, botanist; Loring Whitman, medical student and photographer, and Harold J. Coolidge, Jr., zoologist.

After completing equipment and arrangements at London and Brussels the party will go first to Liberia, medically a *terra incognita,* to make a medical survey which may have important practical bearing, inasmuch as American interests are starting rubber culture on a large scale to free themselves from British monopoly.

Liberia is about the size of Ohio. The Afro-American population is practically limited to a twenty mile strip along parts of the coast. The interior seems to have a considerable population, and from this the labor on the rubber plantations is recruited. The men come down in parties, work for sixty days at a franc a day, and then return. It is stated that some so enjoy the high wages, change of scene and good treatment, that they escape on the return journey and go back to work. Although it seems a well watered country the natives travel only by land. Dr. Strong plans to employ porters, many of whom will be needed for the transport of the scientific instruments, etc., in order to penetrate the interior over as wide an area as possible, making a general survey of human, animal, plant, and insect life. As far as is known the country rises nowhere more than a few thousand feet. So little is known, that on the United States Government map prepared during the late war, several regions are labelled "Cannibal." From Liberia it is planned to ship to and ascend the Congo to its source in or near Lake Tanganyika. Somewhere in this region Dr. Strong plans to study especially, tropical nonmalarial splenomegaly so rife in his experience in the Philippines and Amazonia, and to unravel its origin and meaning; lymph gland enlargement said to be common here, but of, at least, uncertain origin, and to try a new French remedy for sleeping sickness, having been plentifully supplied with it by its originator.

The next leg of the trip, exclusively by leg, goes to Nairobi; the last leg by rail is to Mombasa. The equatorial belt of Africa will thus be traversed. There is of course a considerable factor of uncertainty hanging over such an expedition. After getting on the ground it may be necessary or advisable to modify or change preliminary plans. It is reasonable to hope that such a well manned expedition may result in notable additions to science. The members of the expedition are masters in their several lines of work. They are well equipped and enthusiastic over the adventure. Nine to twelve months are allowed for the trip which holds out high hopes of real contribution to science. It is financed from the modest funds of the Department of Tropical Medicine of the Harvard Medical School, eked out by aid from sympathetic friends.

Obituary.

JOHN HOWLAND, M.D.

Baltimore

Dr. John Howland, one of the world's leading authorities on the subject of pediatrics, died on June 20th following an operation in London. Dr. Howland was professor of pediatrics at the Johns Hopkins Medical School and chief pediatrist to the Johns Hopkins Hospital. He was perhaps most renowned for his work with rickets in children and his demonstration by the cure of many whom he treated that codliver oil and proper diet were the basis of such therapy. His work with other diseases of children, among them tetany and acidosis, was also well known. He was a collaborator of Dr. Emmet Holt in writing one of the standard textbooks in pediatrics, *The Diseases of Infancy and Childhood.*

Dr. Howland was born on February 3, 1873, in New York City, the son of Judge Henry E. Howland. He was graduated from Yale University in 1897, and at once took up practice in New York. In addition to his private practice he served as physician to Willard Parker Hospital and to Saint Vincent's Hospital, as well as pathologist to the Foundling Hospital. In 1911 he was appointed professor of pediatrics at Washington University, St. Louis, where he served until the next year, when he assumed his position at Johns Hopkins.

Dr. Howland was known not only as a great physician, but also as a great man. His interests were wide and varied, but, next to his work, he devoted much of his time to the study of American history. In 1925, together with a brother and sister, he presented to his university, Yale, a fine collection of daguerreotypes of famous characters in the history of the United States during the 1840's, a collection which was begun by his father who was also a graduate of Yale University.

Dr. Howland's genial nature and pleasing personality won for him numerous friends.

CARLOS F. MacDONALD, M.D.

New York

Dr. Carlos Frederick MacDonald, an eminent physician and psychiatrist of international reputation, died at his residence in Central Valley, Orange County, New York, on May 29, 1926, in his eighty-first year. He was born at Niles, Trumbull County, Ohio, August 29, 1845, the son of John and Caroline (Barber) MacDonald, and grandson of Angus MacDonald, of the famous Clan MacDonald of Scotland.

At the age of sixteen he enlisted in the Sixth Ohio Volunteer Cavalry, and served until the end of the war, being under fire for the last time at Lee's surrender at Appomattox. He fought in most of the principal battles of the Civil War. After the Civil War he studied medicine, and graduated from Bellevue Hospital Medical College in 1869. Shortly after his graduation he became assistant physician to Kings County Hospital, and visiting physician to the Kings County Smallpox Hospital and Almshouse. He was connected with the Kings County Lunatic Asylum for several years.

He was medical superintendent of the State Hospital for insane criminals at Auburn from 1876 to 1879, when he was appointed superintendent of the Binghamton State Hospital, resigning in 1881, whereupon he was reappointed to the superintendency of the Auburn State Hospital. Here, in the year 1879, he abolished the use of mechanical restraint in the treatment of the insane, this being the first instance in this country of the absolute disuse of such restraint in a hospital for the insane.

In 1889 he was appointed, by Governor Hill, president of the State Commission in Lunacy, now the State Hospital Commission.

He was professor of mental diseases in Bellevue Hospital Medical College from 1887 to 1898, professor of mental and medical jurisprudence in the New York University and Bellevue Medical College from 1898 to 1906, since which time he had been professor emeritus. He was lecturer on insanity in the Albany Medical College in 1902, and fourth consulting physician of the Manhattan State Hospital for the Insane, and consulting alienist to the Hackensack Hospital.

He was dean of that branch of his profession involving mental diseases, and has been associated, as an expert witness or consultant, with almost every important case of that character in this country during the past decade.

SIR JAMES CANTLIE, M.B., C.M.,

London

Sir James Cantlie, who died in a London nursing home on May 28, 1926, at the age of seventy-five, did great work for tropical medicine and for first aid for the sick and wounded.

He was born at Dufftown, Banffshire, Scotland, in 1851. He received a part of his medical education at Aberdeen University and a part at Charing Cross Hospital, where he gained an intimate knowledge of anatomy and surgery which stood him in good stead during his life in the Far East. In 1877 he paid his first visit to China, becoming one of the founders of the College of Medicine in Hong Kong of which he was dean for a period of seven years. He then became a friend of the man who turned the government of China from an autocracy to a republic. Sun Yat Sen, the man in question, was a pupil of Cantlie at the Hong Kong College. Cantlie and Manson were the means of rescuing Sen from imprisonment in the Chinese legation in London.

In 1883 Cantlie joined the Egyptian Cholera Expedition and after his return to London became surgeon to the hospital at the Royal Albert Docks. He was largely instrumental in founding the Society of Tropical Medicine and Hygiene over which he presided for three years, and he founded in 1898 the *Journal of Tropical Medicine,* of which he was joint editor. He was a large contributor to medical science in the direction of writing, chiefly on tropical medicine and surgery.

From 1885 to 1888 he commanded the Volunteer Medical Staff Corps in London, and in 1914 he founded the College of Ambulance in London. Cantlie was a many sided man and of an adventurous spirit.

Proposed Building for the Psychiatric Institute

New York State Psychiatric Institute and Hospital

SULLIVAN W. JONES, State Architect
New York

The award of contracts for the New York State Psychiatric Institute and Hospital at Riverside Drive and 168th Street, New York, which will function as a part of the Medical Centre, brings to a successful conclusion thirty years of effort by the State Hospital Commission to provide adequate facilities for research into the nature and causes of mental disease and for instruction in the treatment and care of mental disorders. It is made possible at this time through the interest of Governor Smith in the State hospital system. His dramatization of the issue resulted in the adoption of the fifty million dollar bond issue for new hospital construction.

That it should have taken so many years to convince the public and the Legislature of the need of such an institution is not strange when it is realized that it is not much more than a century ago that mental disorder was first recognized as a disease susceptible of scientific treatment.

Under the State Care Act passed in 1890 as a result of a campaign conducted by the New York State Medical Society and the State Charities Aid Association, the State of New York assumed obligation for the care and treatment of the insane and so brought to an end the inhuman custody of these unfortunates in jails, and in county and municipal asylums and almshouses. The last county institution was taken over by the State in 1896, when the State Care Act, passed six years previously, became effective.

The cost to the State of maintaining its system of hospitals for the treatment and care of the insane has increased year after year until today the annual budget, not including the cost of construction, is more than seventeen million dollars. The patient population of the State hospitals has increased from twenty-five thousand to forty-two thousand in the last twenty years and is now increasing at the rate of more than nine hundred a year. Over eight thousand doctors, nurses and attendants are employed by the State in the operation of its fourteen hospitals.

In providing accommodations for this constantly growing patient population the State has fallen far behind in satisfying requirements. In 1924, when the bond issue for new construction at State hospitals and charitable institutions was authorized, there were nearly nine thousand more patients in the State hospitals than there should have been. This condition of grave overcrowding was brought forcibly to the attention of the public as the result of the disastrous fire at Manhattan State Hospital on Ward's Island in February, 1923, when twenty-three patients lost their lives. In the fall of that year the bond issue for new construction was approved by an overwhelming majority by the voters of the State.

In the building program made possible by this bond issue it was natural that the Psychiatric Institute should receive early consideration. Of all the millions made available for medical research by private philanthrophy in this State, not one dollar has been expended for studies designed primarily to throw light on the obscure problems of mental disease. Apparently the State must foster psychiatric research or psychiatric research will not be undertaken at all. It is a most unfortunate circumstance that study of mental disease, because of the State's interest in that branch of medicine, should be in a sense discriminated against by those in a position to lend support to original investigations and scientific studies in this field.

Almost from the beginning of the modernization of the New York State Hospitals twenty-five years ago it was recognized that a central research and teaching department was urgently needed and formed an essential link in the state hospital system. Accordingly, there was first established the Pathological Institute, which later became the Psychiatric Institute, and was moved to Ward's Island where access to Manhattan State Hospital was possible. The provisions actually made for carrying on the scientific work were meagre and inadequate, however. To give the needed facilities for intensive study, research and education is the primary object of the new Psychiatric Institute and Hospital.

The plans provide for a fireproof hospital and outpatient clinic eleven stories high surmounted by a nine story tower that will accommodate the laboratory and research departments of the institution. The utilization of the site at 168th Street and Riverside Drive required considerable architectural ingenuity. At this point there is a difference of a hundred feet between the Broadway and Riverside Drive levels. The hospital is to be built against this embankment. Its main entrance will be on the tenth floor, facing Broadway and assuring easy access to the other buildings of the Medical Centre as well as the subway and street car lines. Entering the building at this point one will find elevators descending to the hospital floors below or ascending to the laboratory floors above. A ramp from Haven Avenue will permit ambulances to discharge their patients at the eighth floor. A separate entrance is provided for outpatients as it is the desire of the authorities to encourage this preventive feature of the work as much as possible.

The building has been designed with the corridor on each of the lower floors in the rear and against the embankment permitting all the wards to face west, giving a view of the Hudson and abundant light and air. Above the Broadway level this arrangement is abandoned, the tower rooms receiving light from all sides.

Beds will be provided for 210 patients of both sexes, including children, grouped in small ward units so that the different types of cases can be separated for study and treatment according to their individual needs. Provision has been made for all the approved and modern diagnostic and treatment facilities which will make possible the use of hydrotherapy, electrotherapy, occupation therapy, light therapy, physiotherapy, gymnastics, psychotherapy, and special medical and surgical procedures. A well equipped dental department will be included.

All varieties of mental diseases will be studied. Admissions will be so controlled that special groups of patients, or special types of disease, will receive preference according to the special researches under way at any given time.

The children's department will constitute an important phase of the clinical work. To it will be devoted an entire floor of the hospital building. The children's wards will be provided with school rooms, work shops, and play rooms. Not only children suffering from definite mental disturbances will receive attention, but also children showing signs of nervousness, emotional instability, backwardness or mental deficiency. Special facilities will be provided for studying children who offer problems in the school and preschool ages. If necessary, such children will be admitted for observation and determination of the plan of treatment. It is generally recognized that there is a great need for intensive study of the instinctive and emotional life of maladjusted children, as these apparently play an important rôle in producing behavior disorders, delinquencies and psychopathic tendencies in children, as well as forming the foundation for many mental disorders which develop in later life. In connection with the outpatient department, a special habit training clinic for children and parents will be provided.

The outpatient department of the hospital will occupy a large part of two floors. Many mild and borderline types of mental disorder can be more satisfactorily handled in an outpatient clinic than in a hospital. Other patients after a relatively short time in the hospital, will be able to return home under the supervision of social service workers and continue their treatment by visits to the outpatient clinic.

It is thought that many persons in the early or incipient stages of mental disease will come voluntarily for treatment and admission to the hospital. In this way a large group of patients will be reached months or even years earlier than under the present unfortunate tendency to avoid a state hospital as long as possible or to use it only as a last resort, usually only after the mental disorder is well advanced. Early treatment will undoubtedly afford relief to many patients and obviate the necessity of commitment to a state hospital. There is little doubt but that the outpatient department will permit many patients to be carried along to improvement or recovery.

The treatment and diagnostic facilities of the institution are so located that they will be readily accessible for the outpatients as well as for the patients admitted to the hospital.

The diagnostic clinic which occupies a large sec-

tion of an entire floor will afford all the necessary facilities for the intensive physical and psychological study of the individual case—outpatients as well as those admitted to the hospital. Specialists in various branches of medicine and surgery, assisted by the resident staff, will conduct the examinations and outline a plan of treatment for each patient.

In the tower will be housed the library and museum, record room, director's office, staff conference room, class rooms, and the various research laboratories. The laboratories will be equipped for making special studies and investigations in the fields of neuroanatomy, neurophysiology, neuropathology, clinical pathology, chemistry, bacteriology, serology, endocrinology, and experimental psychology. The top laboratory floor will be devoted to quarters for animals, with laboratories for experimental work.

The teaching activities of the institution will be carried on in practically all of its departments. Psychiatry has been generally neglected in medical education. Physicians leaving most of the medical colleges of the country today are little better prepared to recognize and deal with the most common forms of mental disease than were their predecessors twenty years ago. Because of having their attention directed to social consequences of mental disease, many groups of laymen are at present better informed than physicians regarding the main facts of mental medicine. Through a close working connection with the College of Physicians and Surgeons, the new institution will provide the first adequate facilities in the State of New York for the instruction of students and physicians in the principles of psychiatry.

A large lecture hall and smaller class rooms and teaching laboratories will afford ample opportunity for these educational activities. Teachers of psychiatry will be enabled to hold clinics and demonstrations and give instruction at the bedside on the wards.

In conjunction with the medical schools of the city postgraduate courses of instruction in psychiatry will be given for practising physicians. Also special courses of instruction will be given for physicians in the state hospital service. Quarters will be provided for state hospital physicians who will come to work for two or three months at a time on the wards or in the laboratories of the institution. It is the purpose to add to the equipment of physicians entering the state service by giving them some preliminary training and instruction before they join the various hospital staffs.

Lecture courses will be arranged for school teachers, social workers, welfare officers and others whose work brings them in almost daily contract with various psychiatric problems.

The sphere of influence of the Psychiatric Institute will be more than local. Situated in New York city, it will have direct contact with a community that furnishes more than half of all the cases committed annually to the state hospitals. Through its teaching and its connection with the Medical Centre it will influence the whole medical world. It will also work in cooperation with various other state departments, with the prisons, reformatories, courts and schools. Furthermore, the institution will be utilized by the State Hospital Commission as a central agency to carry on a systemic statewide educational and mental hygiene program, including exhibits, lectures, local surveys and studies conducted in conjunction with the other state agencies which have psychiatric problems.

It is expected, then, that the new institute and hospital will be an important educational centre as well as a research and treatment centre—a place where information and expert advice may be obtained on all matters relating to mental health. It is believed that the new institution will become one of the most active mental hygiene centres in the country.

News Items.

Summer Courses in Mental Hygiene.—Summer courses in mental hygiene and in special education of the mentally handicapped are being conducted at the Syracuse State School for Mental Defectives in connection with the summer school at Syracuse University. Information may be obtained from Dr. O. H. Cobb, Superintendent, Syracuse State School, Syracuse, N. Y.

Travel Study Club Tour Inaugurated.—Members of the physicians' Travel Study Club of America sailed from New York recently on the Norwegian American liner, *Stavangerfjord,* for a six weeks' tour of Europe. Dr. Louis Livingston Seaman, president of the club, heads the tour. The itinerary will include practically all the larger cities of Scandinavia, Germany, France and England. The tours will take place annually.

Salzschlirf a Health Resort.—The German health and pleasure resort of Salzschlirf is offering room, board and four medicinal baths a week for a period of three weeks at a cost of about $3 a day. Salzschlirf has been especially fitted to receive American patrons and patients by including on its staff a number of English speaking physicians. Sufferers from gout, rheumatism and arteriosclerosis have found this resort of special benefit.

Dr. Roux Retires.—Dr. César Roux, of Lausanne, widely renowned Swiss surgeon, recently resigned as director of the Cantonal Hospital and at the same time announced his intention of giving up also his private practice. Although Dr. Roux has performed many operations for many different kinds of ailments, the name of "king of appendicitis" has clung to him for many years, and patients from all parts of the world came to him for operations in this specialty.

High School Medical Society.—A medical society composed of fourth term boys who intend to become physicians was organized recently at the Thomas Jefferson High School, New York. A condition of membership is a grade of not less than eighty per cent. in first year biology. The boys have received special instruction in hygiene and first aid, and will be taught to assist the medical office of the school in first aid cases. The club has assumed responsibility for first aid at athletic meets.

Civil Service Examination.—The U. S. Civil Service Commission has announced that applications for senior medical technician (pathology) must be on file at Washington, D. C., not later than July 13th. The examination is to fill a vacancy in the Surgeon General's Office, War Department, and vacancies occurring in positions requiring similiar qualifications. Full information and application blanks may be obtained from the U. S. Civil Service Commission, Washington, D. C., or from the secretary of the board of the U. S. civil service examiners at the post office or custom house in any city.

Specialist in Tuberculosis Wanted for India.—A graduate physician who has made a specialty of tuberculosis and who is in sympathy with missionary service ideals, is being sought by the personnel department of the Board of Foreign Missions of the Methodist Episcopal Church for services in India. He would have a hospital of thirty beds, with an opportunity to develop a public health service, and specialization in tuberculosis and hookworm in cooperation with other agencies in the field. The position is open to a graduate physician forty years of age or under, and having a family of not more than two children. The applicant should be a member of an evangelical church. Application and inquiries may be addressed to T. A. Hildreth, Board of Foreign Missions, 150 Fifth avenue, New York.

Psychoanalytical Society Changes Name.—At the May meeting of the Washington Psychoanalytic Society the name of the organization was changed to The Washington Psychopathological Society by a two thirds majority. The last meeting before the summer recess was held on Monday, June 28th. Dr. John H. Cassity read a paper on Psychological Considerations of Pedophilia.

World Conference on Narcotic Education.—The first world conference on education in narcotics is being held in Philadelphia, July 5th-10th. Among members of the conference committee are Robert Lansing, Senator Royal S. Copeland, Speaker Nicholas Longworth, Governor Gifford Pinchot, General John J. Pershing, and Mabel Boardman of the American Red Cross. The conference was called under the auspices of the International Narcotic Education Association, whose founder and president is Richard Pearson Hobson.

New Haven to Fight Tuberculosis.—The city of New Haven has appointed a Muncipal Director of Tuberculosis, Dr. Willard B. Slooper. The appointment was made by the Board of Health acting in cooperation with the National Tuberculosis Association, the Rockefeller Foundation, and the Trudeau Laboratories at Lake Saranac, with which Dr. Slooper was formerly connected. He had charge during the World War of the general hospital at Etretat, France, and has also done work for the Rockefeller Foundation. He has degrees from Yale, Columbia, and Freiberg Universities, and has served in the Presbyterian Hospital, New York City.

Congress of Connecticut Medical Society.—The second clinical congress of the Connecticut State Medical Society will be held in New Haven, September 21st-23rd. All sessions will meet in Sprague Memorial Hall in College Street, corner of Wall. Yale University has assigned one of its dormitories for the use of those attending the congress. Hotel rooms may also be had at the usual rates. The University Dining Hall will be open during the congress. Among speakers will be Dr. Henry Christian, of Boston; Dr. R. G. Hoskins, of Columbus, Ohio; Dr. C. F. Painter, of Boston; Dr. Robert B. Osgood, of Boston; Dr. Edward Livingston Hunt, of New York; Dr. J. Shelton Horsley, of Richmond, Va.; Dr. Frederic J. Cotton, of Boston; Dr. A. C. Christie, of Washington, D. C.; Dr. R. G. Dennett, of New York; Dr. Hugh Cabot, of Ann Arbor, Michigan; and Dr. John Osborn Polak, of Brooklyn, N. Y.

Personal.—Dr. Adolph Rostenburg has been appointed to the position of attending dermatologist at the New Sydenham Hospital, New York City.

Dr. Justin Herold, of 17 East Thirty-eight Street, New York City, left on June 12th on the French liner, Paris, for a visit to France and Germany. Dr. Herold has practised medicine in New York City for nearly fifty years.

Dr. Smith Ely Jelliffe of New York City has been made a corresponding member of the Vienna Society of Neurology and Psychiatry.

Dr. William C. Menninger, hitherto of New York City, has joined the staffs of the Menninger Neuropsychiatric Clinic and the Menninger Psychiatric Hospital in Topeka, Kansas. Dr. Menninger will limit his practice to the interrelations of internal medicine and neuropsychiatry.

Dr. Nathan E. Broder has been appointed associate obstetrician to the People's Hospital, New York City.

Dr. William H. Godsick and Dr. Irving Smiley have been appointed assistant attending gynecologists and obstetricians at Lincoln Hospital, New York City.

Dr. William Seaman Bainbridge read a paper on Cancer Today before the American Therapeutic Society, at its annual meeting in Philadelphia. He also read a paper on the Present Status of the Cancer Problem: A Résumé before the Middlesex County Medical Society of New Jersey, at its quarterly meeting.

Dr. Joseph P. Eidson has been appointed chief of the psychiatric clinic of the Cornell Clinic in New York City.

Dr. Philip J. Trentzsch has been appointed psychiatrist to the Culver Military Academy at Culver, Indiana. The Culver Academy is the first secondary school in the United States to number among its staff members a full time psychiatrist.

State Senator of New York, William Lathrop Love, a physician, and Alexander Marky, formerly a magazine editor, debated recently in New York City the question of Vaccination and Antitoxin.

Journées Médicales in Paris.—The French Republic has organized for the benefit and entertainment of French and foreign medical men visiting Paris during the summer a series of *journées médicales*, extending from July 15th-20th. Features of the occasion will be the opening on the 15th of the Medical Exposition at the Grand Palais, a visit to the Pasteur Institute on the 17th, and a visit to historic Rheims on the 19th. In addition, there will be numerous visits to clinics and institutions of interest, lectures, concerts, moving picture demonstrations, receptions, etc. During the course of the *journées*, it is hoped that an international union of practising physicians will be organized under the auspices of the Union of Medical Syndicates of France. Dr. Dujarric de la Rivière, 18 rue de Verneuil, Paris, 7e, is in charge of arrangements for participating in the *journées*.

Conventions at the Sesquicentennial.—Among meetings to be held at the Philadelphia Exposition are the American Pharmaceutical Association, August 15th-21st; Pennsylvania State Dental Society, August 23d-28th; International Dental Congress, August 23d-28th; National Medical Association, (Colored), August 24th-27th; American Chemical Society, September 6th-11th; National Association of Retail Druggists, September 20th-24th; American Library Association, October 4th-9th; and the Special Libraries Association, October 18th-22d.

Appropriation for Community Mental Hygiene.—The Commonwealth Fund of New York, founded by Edward S. Harkness, has appropriated nearly $400,000 for one year's work in a comprehensive program for community mental hygiene. That is said to be the largest sum ever set aside for work in mental hygiene during a year. The organizations participating are the National Committee for Mental Hygiene, the Bureau of Child Guidance of the New York School of Social Work, the National Committee on Visiting Teachers, the Smith College School for Social Work, and the Joint Committee on Methods of Preventing Delinquency. The new program provides for the establishment of an Institute for Child Guidance, which will supersede the present Bureau of Child Guidance of New York City and will absorb $170,000 of the total appropriation.

Gifts and Bequests.—A fund of $300,000 to found the John E. Borne Chair of Medical and Surgical Research in the College of Physicians and Surgeons of Columbia University, is provided for in the will of Mrs. Ellen Mills Borne, widow of John E. Borne, who died in 1910. Among additional bequests are $15,000 to the Long Island College Hospital, and $3,000 each to the American Society for the Prevention of Cruelty to Animals and to the Playground and Recreation Association of America.

The will of the late Ella A. Rogers contained among other public benefactions bequests of $50,000 to New York Hospital, $25,000 to Lincoln Hospital, $25,000 to the Servants of Relief for Incurable Cancer, $20,000 to St. Mark's Hospital, and $10,000 to the Home for Incurables.

Mrs. Stephen V. Harkness has given $100,000 to New York Homeopathic Medical College and Flower Hospital to endow a department of physiology, thus raising the endowment fund to $500,000. The gift is a memorial to the late Dr. E. Guernsey Rankin, after whom the new department will be called.

At the luncheon of June 19th of the Bankers' Club, with Thomas W. Lamont and J. P. Morgan presiding, announcement was made of gifts of $199,500 toward the million dollar endowment fund for the American Society for the Control of Cancer. This brings the total to $338,515.

By the will of the late Louis Sherry, the endowment for the J. Bentley Squier Urological Clinic at the new Columbia-Presbyterian Hospital Medical Center will be increased by approximately $700,000. This will bring the sum available for the clinic to about $1,300,000. Mr. Sherry also provided that any income above that necessary to provide for his wife shall go to the clinic, thus establishing a fund to be known as the Bertha Sherry Memorial Fund. An anonymous gift was recently made to the Bentley Squier Urological Clinic amounting to approximately $200,000. This took the form of a pledge to pay $1,000 a month, in perpetuity toward a fund for maintaining ward patients in the clinic.

The will of the late Dr. Julius Rudisch provides, in a contingent bequest, that his estate of "more than $50,000" shall ultimately be divided between the New York physicians Mutual Aid Association and Mount Sinai Hospital, of New York.

Book Reviews

GYNECOLOGY

Gynecology for Nurses. By M. J. Seifert, A.B., M.D., F.A.C.S., Attending Surgeon and Gynecologist, Columbus Hospital, Chicago. New York and London: D. Appleton & Company, 1925.

An excellent work, evidently the result of an extensive practical experience on the part of the author. The reader gradually passes from the basic subjects of the anatomy, physiology and pathology of the female generative organs to a consideration of special conditions which constitute the major conditions with which gynecology deals. The text is written in a clear and concise manner, illustrations are standard in character but well drawn, and the printing is excellent. Special chapters written by special contributors include a section on gynecological urology, one on radiotherapy and another on endocrinology. Twenty pages are devoted to the subject of diet in gynecology, and it is to be hoped that the appetizing menus here recorded will not have been written in vain, but will find a place in the actual dietary of gynecological hospital wards. The volume concludes with a useful chapter on medical terminology, including a copious list of prefixes, suffixes and roots of the most commonly used medical terms. On the whole, the book is excellent and ought to be exceedingly useful to the student or graduate nurse.

MATERIA MEDICA AND THERAPEUTICS

Materia Medica and Therapeutics. Including Pharmacy and Pharmacology. By Reynold Webb Wilcox, M.D. Philadelphia: P. Blakiston's Son & Company, 1926.

This excellent book has reached its eleventh edition. The author states in his preface that this new edition was made necessary by the appearance of the Tenth Revision of the United States Pharmacopeia. He describes a number of drugs and preparations that might as well be deleted, and especially should such substances as orange, lemon, honey, wax, suet, etc., be omitted from a medical book. The author has not seen fit to change the doses of liquid preparations from "mils" back to "cubic centimetres" to conform to the last edition of the Pharmacopeia. It will be remembered that the only edition of the Pharmacopeia that ever adopted a dosage of mils was the ninth edition.

It is too bad, on page 26, to perpetuate the absurd prescription there outlined, namely, tincture of the chloride of iron 12 mils, quinine hydrochloride 2 grams, magnesium sulphate 60 grams, glycerin 60 mils, and water, ad 240 mils, in which the directions are to take a "teaspoonful three times daily, two hours after meals." It would be impossible to have any patient, at the present day, take such a nauseating dose as above directed. In modern medical times such a prescription is inexcusable.

There is too much favorable comment concerning the use of iodoform; it certainly should not be used freely for dressings, as there is danger of absorption and poisoning. Boric acid should never be used internally; the author is a little too generous at times in stating old uses of drugs. Also there is no use for potassium permanganate internally, except as an antidote, in the stomach, to morphine poisoning.

With these few mild criticisms the reviewer highly commends the book for the use both of students and practitioners. The pharmacology is brief and up to date, and the therapeutic advice is good.

SURGICAL CLINICS

The Surgical Clinics of North America. San Francisco Number. Volume 6, Number 2. Philadelphia and London: W. B. Saunders Company, 1926.

Twenty clinics are presented in this number of the well known *Surgical Clinics,* representing various San Francisco hospitals. The subjects of these clinics vary considerably, as is generally the case, ranging from hammer toe to cerebral anemia. L. A. Emge offers an unusually interesting clinic on Varicose Veins of the Female Pelvis; E. I. Bartlett and C. L. Callander discuss the subject of Neck Dissections, while Frank Hinman presents an interesting contribution on the Experimental Study of the Pathogenesis of Hydronephrosis. Seventy-three excellent illustrations contribute to the value of this volume. It may be said that the general high standard of previous issues has been fully maintained in the volume under review.

WASSERMANN REACTION

The Clinical Interpretation of the Wassermann Reaction. By Robert A. Kilduffe, A.B., A.M., M.D., Director, Laboratories, Atlantic City Hospital, etc. Illustrated. Philadelphia and New York: Lea and Febiger, 1926.

The author has presented the case of the Wassermann reaction concisely and clearly. With some of his views, many will differ; with most, all will agree. Much attention is given to the matter of misinterpretation of the test, due, unfortunately, to the fact that it is more frequently applied than wisely interpreted. The author maintains that much of the misinterpretation of the test is due to the influence of conceptions coincident with its discovery and early application, such as the erroneous idea of a true biological specificity, the fear of widespread false positive reactions in a host of varied diseases, or the unwarranted clinical significance attached to a negative reaction and so on; conceptions which the prolonged and extensive studies conducted in more recent times have shown to be fallacious.

Unfortunately, the clinician still is faced by the difficult problem of reconciling contradictory results in identical serum obtained simultaneously by different serologists, as emphasized by Wolbarst and other clinicians. A careful search through this volume does not reveal any mention of these contradictions. True, they cannot be explained, inasmuch as they have been found to occur in the work of serologists whose reliability and technical integrity are beyond question. The conscientious clinician therefore may be pardoned for expressing a somewhat lessened enthusiasm in the universal efficacy of this most valuable test.

Regarding the value of the reaction in primary syphilis, the author rightly says that the earlier the lesion, the more valuable the dark field examination; the older the lesion, the more valuable the complement fixation test. In this teaching lies much wisdom, which it would be well for the general practitioner to learn. The same may be said of the au-

thor's statement regarding the test in untreated secondary syphilis, to the effect that a positive reaction does not necessarily indicate the syphilitic nature of the immediate or presenting symptoms. This presupposes a knowledge of clinical syphilis, a subject which the laboratory diagnosis is converting into one of the lost medical arts. The author quotes, in evident agreement: "A product of our modern methods of diagnosis and treatment is the pseudosyphilographer. For him the clinical study of syphilis is unnecessary. The public Wassermann laboratory makes the diagnosis without charge and a few injections of arsphenamine clear up the lesions." It is unfortunate, but true, that the laboratory diagnosis has done much mischief, not only by stamping a wrong diagnosis upon the hapless victim, but by robbing the practitioner of the ability and the courage to make a clinical diagnosis when that is possible. It were well if the practitioner could accustom himself to the thought that a positive seroreaction is one of the symptoms suggestive of the presence of syphilis—not the complete diagnosis.

The work under review is one which every practitioner of medicine can read and study with profit. The complement fixation test has reached the stage in medical practice in which it must be accepted as a most important diagnostic aid, but it is of the utmost importance that the practitioner should clearly understand not only its transcendent value, but also its limitations and the pitfalls which await him who misinterprets its findings. A careful study of this little volume will reveal these pitfalls and lead to a better understanding and greater appreciation of the test and its utility in syphilis.

PHARMACEUTICAL CHEMISTRY

A Text Book of Pharmaceutical Chemistry. By Arthur Owen Bentley, Ph.C. Director of the Department of Pharmacy, University College, Nottingham, and John Edmund Driver, M. Sc. (Lond.), A. I. C., Lecturer in Chemistry, University College, Nottingham. Oxford University Press. London: Humphrey Milford, 1925. Pp. 456.

With the raising of the standard of the education of the pharmacist comes a corresponding improvement in the textbooks which he must use. This volume of pharmaceutical chemistry, while it is based particularly on the British Pharmacopeia, will certainly prove a useful text for American students. There is included a considerable amount of qualitative and quantitative technic in addition to the purely descriptive chemical material. The whole subject of pharmaceutical chemistry is admirably treated.

QUALITATIVE ANALYSIS

A Systematic Course of Qualitative Chemical Analysis of Inorganic and Organic Substances, with Explanatory Notes. By Henry W. Schimpf, Ph.G., M.D., Professor of Analytical Chemistry in the Brooklyn College of Pharmacy. Fourth Edition. Revised by Alfred I. Cone, Phar.D., Ph.G. New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Limited, 1924. Pp. 201.

The fourth edition of this standard guide for qualitative analysis has been considerably improved in the part devoted to the determination of the various synthetic drugs, and brought up to date in the portion devoted to inorganic substances. It remains one of the best of the smaller texts of qualitative analysis for pharmacy students.

BLOOD CHEMISTRY

Blood Chemistry. Colorimetric Methods for the General Practitioner With Clinical Comments and Dietary Suggestions. By Willard J. Stone, B. Sc., M.D. Second Edition, Revised. Introduction by George Dock, M.D. New York: Paul Hoeber, Inc., 1926. Pp. 129.

This laboratory manual of blood chemical work follows the traditions laid down for such texts. Each method has the logical arrangement into, 1, solutions used; 2, preparation of solutions; 3, final step, and 4, calculation. The procedures are all very clearly explained. The book differs from most laboratory guides of similar nature in having at the end of each determination a page or so of clinical comments, and the two final chapters are devoted to the dietary control of disturbances of metabolism, and brief comments on the diet in diabetes mellitus. In those communities where the knowledge of the interpretation of blood chemistry determinations is not so diffused as it is in the larger hospital centres, the inclusion of the clinical comments will be a particularly useful feature.

MONTEFIORE HOSPITAL ACTIVITIES

Collected Reprints. Montefiore Hospital for Chronic Diseases. New York. Volume IV, 1925.

The material seen at the Montefiore Hospital is varied, and offers an opportunity for the study of chronic diseases that the wards of other hospitals, generally more devoted to the rapid turnover of acute surgical cases, or to medical cases which come and go, do not have. The reprints in this volume reflect also the varied activities of the Montefiore Hospital, from studies on crown gall disease, to those on some phasic and permanent mutations in certain encephalitic syndromes. The volume is divided into the following sections: cardiovascular system; metabolism and internal secretions; nervous system; gastrointestinal system; tumors and tumor therapy, and a general section, dealing mainly with the care of the sick poor. This is an interesting collection of reprints.

ROCKEFELLER INSTITUTE STUDIES

Studies from the Rockefeller Institute. Volumes LIV and LV. New York: The Rockefeller Institute for Medical Research, 1925 and 1926.

These two volumes containing collected reprints, each totalling some six hundred pages, are an effective tribute to the industry of one research institution in America: The Rockefeller Institute. The collected papers cover studies in pathology and bacteriology, biophysics, chemistry, experimental surgery, general physiology, animal pathology, and studies from the Hospital of the Institute. Many of the articles have already been abstracted in these pages.

MEDICAL RESEARCH IN AUSTRALIA

The Walter and Eliza Hall Institute of Research in Pathology and Medicine, Melbourne: Collected Papers. Volume II, 1923-1925.

This is an interesting collection of reprints of twenty-two papers which have appeared in various Australian medical journals within the past two years. Of these, seven deal with the study of hydatid disease of the liver, the use of Casoni's reaction in its diagnosis, etc., and several others with the complement fixation test in tuberculosis.

Medicoliterary Notes.

The Annual Report for 1925 of the Health Organization of the League of Nations has recently been issued.

* * *

Birkbeck College of the University of London has organized among its students a movement for reducing the suffering caused by cruelty to animals throughout the world.

* * *

Endemic Goitre and Intelligence is the title of a study published in *Public Health Reports* for May 21st. By Robert Oleson, Surgeon, U. S. Public Health Service, and Mabel R. Fernald, Ph.D., Director of the Psychological Laboratory of the Vocation Bureau of the Cincinnati public schools.

* * *

Dr. Bailey Willis, professor emeritus of geology at Leland Stanford University, has recently announced through the press that local business interests near San Francisco are introducing a program, inaugurated by the Carnegia Institution of Washington, for the "microscopic" study of earthquakes with a view to preventing such damage as that suffered by San Francisco in 1906 and by Santa Barbara in 1925.

* * *

The Harmon Foundation, through the Survey Associates, has offered three prizes of $250, $100 and $50, respectively, to be awarded for the best unpublished manuscripts dealing with some experiment, invention or achievement in the field of public health. The winning papers will be published in the *Survey* and collaborating periodicals.

Dr. C. A. Magoon, of the Bureau of Plant Industry of the U. S. Department of Agriculture, has recently announced through an article in the *Journal of Infectious Diseases,* that he has been able, by a process of selection, to produce a strain of bacterial spores twenty-five times as resistant to heat as the original spores with which he started his experiments. Dr. Magoon concludes his article by saying: "More information upon this important subject is greatly needed, for, until more is known of the reasons for these differences, satisfactory and reliable methods of spore destruction cannot be developed, and the technology of food preservation will continue to be subject to the laws of chance."

The statement has been accredited to Prof. Walter L. Whittlesey, of the Political Department of Princeton University, that American independence was not born on the Fourth of July, nor was the Declaration of Independence signed on that date. "What was done on our first Fourth," said Professor Whittlesey, "was only to agree to the final draft of the poster which John Dunlap printed on the night of July 4, 1776, for public distribution. By that date our thirteen original States had been solemnly and officially independent for two days. The tie with Great Britain was cut by resolution of Congress on July 2d.

A new agricultural poison, calcium cyanide, is being found most effective in ridding trees and plants in southern California of insect pests. Calcium cyanide, while theoretically appearing to be a simple preparation to the ordinary chemist, is impossible to make in any ordinary way. By combining calcium carbide with hydrocyanic acid, however, a light brown powder is secured and this substance has the power of pouring a veritable wave of poison gas when it is merely exposed to common air. Fumigators simply blow the poison in a dust cloud under the regular orchard tent, with death dealing results to any living creature that may be beneath it.

According to the recently published report of the National Bureau of Casualty and Surety Underwriters, automobile fatalities in the United States in 1925 increased approximately 2,200 over those in 1924. In 1925 the total number was 22,500; excluding collisions with street cars and railway trains, they increased from 17,600 in 1924 to 19,800 in 1925; fatal automobile grade crossing accidents rose from 1,688 in 1924 to 1,784 in 1925. The automobile death rate per 100,000 increased from 14.9 in 1923 to 15.7 in 1924, and to 17.2 in 1925. This means that the increase in 1924 was five per cent.; in 1925 it was nearly ten per cent. In 1925 approximately 6,300 children under fifteen years of age were killed by automobiles, as compared with 6,090 in 1924.

China has more than two hundred distinct currencies in use, some of which are good throughout the country, some in only a few of the provinces, and some only in the section where they originated.

Abstracts from Current Literature

GYNECOLOGY AND OBSTETRICS

Interagglutination of Maternal and Fetal Blood in the Late Toxemias of Pregnancy.—Wilmar M. Allen (*Bulletin of the Johns Hopkins Hospital,* March, 1926) studied the isoagglutination relationship in 479 mothers and their newly born infants. Of these 375 were normal and 104 toxemic women. The tests showed no evidence that incompatibility was more frequent in toxemic than in normal gestation. Incompatibility between the bloods of mother and infant was present in 20.8 per cent. of the normal and 21.1 per cent. of the toxemic pregnancies. There is no evidence of an increased agglutinin titer in the maternal serum of toxemic women, nor of specific immunization of the mother against fetal corpuscles. The discrepancy between this and previous work is probably accounted for by the size of the series studied. With a small number of cases the percentage of error and likelihood of coincidence are very great. The study of this series of cases, by the methods used, give no evidence that the late toxemias of pregnancy have their origin in isoagglutination phenomena.

Basal Metabolism in the Toxemias of Pregnancy.—H. J. Stander and C. H. Peckham (*Bulletin of the Johns Hopkins Hospital,* March, 1926) studied the basal metabolic rate of women during pregnancy, which showed the same gradual increase during the latter half as already reported by other authors. The return to normal occurred at about the tenth day of the puerperium, and was gradual and steady. In preeclamptic toxemia the basal metabolic rate is slightly higher than in normal pregnancy. It returns to a normal level about the fifteenth day of the puerperium. Nephritic toxemia is associated with a basal metabolic rate of about +33 before delivery. This figure is slightly higher than that for the preeclamptic group. The tendency for the basal rate in nephritic toxemia is to stay high for a longer time during the puerperium than it does in preeclampsia. The basal metabolic curve for the eclamptic group is almost identical with the nephritis curve. Basal metabolism determinations do not prove of any real help in differentiating between the various types of toxemias in late pregnancy. In normal pregnancy, as well as in the different toxemias of pregnancy, there is some factor or factors which result in an elevated basal metabolic rate as term is approached, a gradual return to normal ensuing during the puerperium. It is probable that such factor, or factors, may have to do with the growing product of conception, as well as a slight increased activity of the thyroid gland.

Latent Syphilis and Pregnancy.—E. Bertin (*Presse Médicale,* March 3, 1926) states that for several years the frequency of overlooked syphilis in women has been attracting attention. It is a striking fact that in many women syphilis may remain latent for many years and be suddenly revealed by an abortion, a premature delivery with death of the fetus, or the birth of a child with unmistakably syphilitic lesions. Not rarely apparently healthy women are delivered of a fetus or child whose syphilis contrasts in its virulence with the mother's health; such women, indeed, remain well for many years or even throughout life. In some, the serum reactions, after having shown an active syphilis, become completely negative. This type of maternal syphilis is very mild, in fact quite extraordinarily mild, at its onset. The same has been true, in the author's experience, of the source of infection. Although syphilis is usually transmitted by an early, active lesion, he has seen it transmitted six, seven or ten years after the chancre by well informed, cautions men (physicians) thoroughly aware of the danger from the least genital erosion. Most of these infections of women which are unusual in their mildness of outset have been transmitted by husbands who have been under treatment for a very long time. It appears that these latent cases of syphilis in women may under certain physiological or pathological conditions be whipped up to become suddenly virulent. Pregnancy is one of the commonest and most potent of these factors. In general, the latent spyhilis is grave more particularly to the fetus; in the mother, indeed, a succession of miscarriages seems to attenuate her own infection. The relative mildness of the infection in spite of an impressive series of miscarriages which would seem to indicate that it is severe may be compared to the observations of cases of syphilis which have particularly intense lesions of the skin and mucous membranes at the start, but which, as shown by experience, are ultimately the mildest, even when they have recurrences. In such cases the infection seldom localizes later in the major viscera or nervous system. Intense localization of the infection in certain structures in all likelihood confer a certain degree of general immunity which protects the individual from other manifestations of the disease. At all events, the apparent mildness of the occult forms of syphilis is not to be relied on. It is therefore important that such cases shall be detected and treated, not only in the interest of the patient, but in that of society. These conceptional forms of syphilis seem commoner nowadays, partly or wholly because syphilis, treated vigorously in the dispensaries and in private practice, has lost some of its virulence without, unfortunately, being extinguished altogether. Obviously there is need of increasing prophylactic endeavors, in particular in the field of prenatal care.

Lipiodol in the Diagnosis of Pregnancy.—Carlos Heuser (*Lancet,* November 28, 1925) states that when a period or two is missed by a woman one can never be quite sure of a pregnancy, for the uterus might be small or it might be anteflexed or retroflexed. In such cases a precise diagnosis is only possible by the use of x rays to show whether the uterine cavity is occupied or not. The injection of lipiodol into the uterine cavity, in the author's experience, never produced abortion and the roentgenograph enabled him to make a positive diagnosis.

The following fixed rules are laid down: When a woman after conception, and after one or more missed periods, wants to know if she is pregnant, and the clinical examination is indecisive, lipiodol may be injected into the uterus. A roentgenograph should then be taken in order to give absolute certainty.

If the injection has been successfully made the roentgenograph of the uterine cavity filled up with lipiodol shows:

1. That the cavity is not well filled if the fetus is more or less developed, the lipiodol penetrating around the fetus, and showing that the cavity is occupied.

2. The round shape of the stain with the roentgenograph of a tube together with the clinical symptoms indicating pregnancy.

3. When the fetus is larger, the liquid penetrates very little, in a line more or less curved, and the form of the roentgenograph of the uterus indicates the pregnancy.

4. If the period is missed once or twice and the patient thinks herself pregnant, the injection of lipiodol into the uterine cavity may show in triangular shape, and at the same time one or both tubes may fill up with the liquid. In such a case the roentgenograph shows that the uterine cavity is unoccupied and there is no pregnancy.

5. Every roentgenograph of the uterine cavity must be complete in order to show the neck and cavity for a satisfactory diagnosis to be made from it, together with the clinical symptoms.

6. The roentgenograph may thus allow us to diagnose sterility due to obstruction of the tubes; for it may be observed that they do not fill or fill up badly.

7. In cases of pyosalpingitis and old salpingitis a roentgenograph of the tubes can be obtained and the diagnosis confirmed.

This method was applied to all patients who presented themselves without any special selection and without any disturbance further than a careful disinfection of the vagina and the bladder. A mild laxative is given to clear the bowels. Four hours before twenty to thirty drops of opium are given to quiet the patient. After thorough sterilization of the vagina and cervix, one to two c.c. of lipiodol are injected, the roentgenograph is taken, and, if possible another two to five c.c. are injected and a second roentgenograph is taken. At the same time, if a better roentgenogram is wanted, forty to sixty c.c. of air may be injected into the bladder. The patient must lie on her shoulders and in the Trendelenburg position.

When there is doubt in the diagnosis between a tumor and pregnancy two to five c.c. of lipiodol is injected on the

first day, and on the following day air is injected into the tubes in order to cause a pneumoperitoneum of 150 to 200 c.c., the patient being in the Trendelenburg position. To show the uterine cavity, five to ten c.c. of lipiodol is injected carefully. When the liquid enters the tubes it produces a little colic and a characteristic pupillary reaction—first a dilatation and then a contraction of the pupils. If the woman has had salpingitis the reaction is much stronger, but there is no pain. If the tubes are obstructed, they do not fill up. It may be necessary to persist with the injection once or twice more in order to fill the tubes.

To determine the permeability of the tubes, whether for the diagnosis of sterility or of salpingitis, the technic is different. The preparatory treatment is the same as above. Then ten to twenty c.c. of the liquid are injected into the uterus with a big cannula, the cervix of the uterus being well closed in order to avoid the passing of the lipiodol into the vagina. The bladder is then filled with air. In the presence of salpingitis the tubes do not fill up with the first injection, and it is necessary to repeat the injection until a good roentgenogram is obtained. In this way the causes of sterility can be determined, whether they be obstruction of the tubes or malposition. Twisting of the tubes can be visualized. In the presence of a tumor of doubtful nature, a pneumoperitoneum is induced by way of the tubes. By this means the clear space in the pelvis due to the pneumoperitoneum reveals the tumor of the uterus and the relations of both to other organs.

Cyesedema: A Peculiar Bloating of Pregnancy.—A. A. Lendon (*British Medical Journal,* December 19, 1925) calls attention to a peculiar bloating or swelling, which is quite distinct, on the one hand, from anasarca or ordinary pitting dropsy, and, on the other hand, from the solid swellings, such as myxedema, which it certainly more nearly resembles. It was observed in six out of 363 cases.

It affects the whole body, but naturally it attracts more attention in the face, as it so greatly alters the features of a young woman as almost to make her unrecognizable towards the end of pregnancy. The author has seen it only in primiparæ; it disappears with considerable rapidity after the labor is over. It has not recurred in the author's cases in subsequent labors; though not specially associated with postmaturity according to the maternal reckoning, the babies have been large. In two cases there was some albuminuria, but no other recognized indication of the socalled toxemia of pregnancy. There are none of the signs of myxedema or renal edema. There is rather some lividity and there is no high blood pressure.

What is its nature? It is certainly not due to nephritis and hypothyroidism may be ruled out of the question. Williams suggests that it may be related to hypertrophy of the anterior lobe of the pituitary body, which, he says, has been "shown to undergo regularly great hypertrophy during pregnancy and to atrophy after the termination of the pregnancy."

Treatment of Cervical Catarrhs with Animal Charcoal.—Fr. Chr. Geller (*Zentralblatt für Gynäkologie,* January 16, 1926) asserts that specific therapy is usually directed toward the vagina in catarrhs of the uterine cervix, and this is the very reason why such treatment is often unsuccessful. The cervix itself is much too often neglected. This neglect of the cervical mucosa is based upon the fear of spreading the infection after intracervical therapy. But this danger has been too much overestimated. The menstrual hyperemia, desquamation and regeneration of the mucosa is a powerful factor in the prevention of the spread of the infection.

Urged on by the favorable results of the socalled biological therapy of leucorrhea, the author has attempted to treat this condition most conservatively by making the bacteria and their toxins innocuous and eliminating them. The intracervical methods of treatment used heretofore have the disadvantage that they injure the cervical mucosa either mechanically (curettage), thermically (cauterization) or chemically (cauterization by chemicals) and so reduce the natural powers of resistance of the tissue. The author has tried an indifferent therapy patterned after the powder insufflation of the vagina and the bolus and charcoal treatment of infectious intestinal catarrhs. The curative power of the pulverized animal charcoal is due to the marked adsorption of the bacteria and their toxins and of the wound secretions. Not only are the bacteria sucked up, but the conditions of life for bacteria are made difficult by the simultaneous drying of the tissues. There is no injury to the cells of the tissues and a hyperemic stimulus upon the tissues is exerted by the abstraction of water.

The only indication for this form of treatment is chronic cervical catarrh. The cases should be carefully selected. Positive gonorrhea is a contraindication, as is also adnexal inflammation.

For the insufflation of the powdered charcoal the author has devised a special cervix powder blower. The instrument and the charcoal must be sterilized. The technic or insufflation is the following: The patient and the physician are prepared as for a curettage. About a quarter of a teaspoonful of powdered charcoal is placed into the insufflator. The vagina and cervix are disinfected and dried as much as possible. The cervix is dilated with a Hegar dilator and the insufflator is immediately inserted into the cervix. Two or three pressures are then made on the hand bulb, after which the insufflator is withdrawn.

Certain Cardiovascular Conditions in the Pregnancy of Normal Women, Including the Response to Efficiency Tests.—Dorothy C. Hare (*British Medical Journal,* November 7, 1925) submitted pregnant women to the following tests: Pulse rate, lying, sitting and standing; also after an easy standard exercise, when the rates noted were: 1, the maximum after exercise; 2, the rate at one and a half minutes as compared with the resting rate; 3, the total number of beats during two minutes after exercise. Blood pressures, lying and sitting, were recorded.

The results showed for the most part a high degree of normality in the adjustments of circulation. One may say that the rate of the pulse, whether lying, sitting, or standing, is normal, though in the eighth month there is a slowing of the pulse rate when sitting as compared with lying, which may be associated with the position of the uterus and pressure on the diaphragm.

The exercise test was well performed throughout, but the return of the pulse to the resting state after the exercise is slower in the earlier months; this may mean that the efficiency is less, but in other tests it appears that the fourth month is a period when the heart is more easily excited to a rapid rate than later in pregnancy.

Blood pressures show no tendency to rise with the advance of pregnancy and are indeed throughout on the low side of normal.

The application of the knowledge gained by physiological tests is obviously important to the better understanding and treatment of pathological conditions.

Sound Sign in Retroflexion of the Uterus.—H. Stribrny-Silber (*Zentralblatt für Gynäkologie,* November 7, 1925), utilizes the sound sign to differentiate between a freely movable and a fixed retroflexion of the uterus. The sound is carefully introduced to elevate the uterus and the behavior of the sound is observed. A fixed retroflexion is indicated by an elastic rebound of the sound which anteflexes the uterus at the moment when the sound is released by the retaining hand (positive sign). This rebound is explained, naturally, by the traction of the adhesions drawing the uterus backward. If the sound does not rebound, but remains in the position of anteflexion imparted to it, or if it falls back slowly from its own weight, the sign is negative and the uterus is considered as movable.

With the positive sign, cases of fixed retroflexion of the uterus include, in the first place, those in which the retroflected uterus itself is adherent to the neighboring structures by adhesions, those in which inflammatory changes of the adnexæ lead to a mediate fixation of the uterus, and those in which the fixation of the uterus consists only in a limitation of its free movement as a result of impinging tumors (myomas and adnexal tumors). We must also include the cases in which the spatial limitation is produced not by the genital organs themselves, but by the bony pelvis. It has been observed that the elevation of the uterus that in itself is movable is possible only when the sound is directed laterally to the markedly prominent promontory; in these cases the sound sign is positive when the promontory is not avoided, because the uterus and the sound then are caught by it.

Movable retroflexion—the negative sound sign—occurs when the uterus is absolutely free from adhesions. If the adhesions are only few and delicate, the sound sign may be negative. In these cases, bimanual examination leads to the correct diagnosis, because the elevation of the uterus, as a result of the traction on the peritoneum, is markedly painful

because of the adhesions, and the uterus again resumes its previous position in spite of a successful elevation. These cases are the borderline cases, as the adhesions of the uterus are not sufficiently strong to exclude an elevation, and thus make the sound sign appear to be positive. This group also includes some cases in which there is a mediate fixation of the uterus from disease of the adnexæ. If the adnexal changes are marked and firm and also bilateral, the uterus is naturally fixed and the sound sign is unquestionably positive; but if they are less pronounced, they may result in movability of the not mediately fixed uterus, which may make the determination of the sign difficult.

This maneuver is contraindicated only in pregnancy and acute infectious cervical catarrh; in all other cases, especially with tense abdominal walls, a fat abdomen and in virgins, this is the best means of differentiating the movable from the immovable retroflexion of the uterus.

Diagnosis of Gonorrhea in the Female.—As a result of some clinical studies, William G. Schultz (*Zentralblatt für Gynäkologie,* November 7, 1925) comes to the following conclusions:

1. In more than ninety per cent. of all the cases of gonorrheal infection examined, the cervix uteri and urethra were involved simultaneously.
2. The process of labor has no demonstrable influence upon the localization of the gonococci in its anatomical clinical sequelæ.
3. The vaginal mucous membrane appears to be predisposed to gonorrheal infection only in juvenile, pregnant and senile women.
4. In over seventy-five per cent. of all cases of gonorrhea of the female genitals, a rectal gonorrhea was present at the same time.
5. The secretions from the urethra and cervix can be obtained in a pure state only when the smear is taken after the urethral meatus and the cervix are previously thoroughly cleansed.
6. A urethral smear should be taken only two hours after the last urination.
7. In almost ninety-nine per cent. of the cases the secretion, taken under proper conditions, was sufficient for the microscopic diagnosis.
8. A practically valuable decision as to the result of a microscopic examination of the secretions should be given in chronic gonorrhea only after at least five smears have been taken, provided gonococci have been demonstrated previously.
9. A provocative test should be made in all cases that remain suspicious after five negative smears.
10. The comparative best results are obtained with a combination of the mechanical, chemical and biological provocative tests with at least ten subsequent smears from the urethra and cervix uteri.
11. Not only extracellular and intracellular gram negative diplococci occurring in groups, but even isolated gram negative diplococci of the typical coffee bean shape are characteristic for the presence of a gonorrhea.

A Symptom Group Met With in Women During the Period of Reproductive Ability.—A. C. Guillaume (*Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris,* March 4, 1926) calls attention to a group of disturbances sometimes observed in women in the period comprised between puberty and the menopause. It is characterized by: 1, Disturbed circulation in the hands and feet; 2, sympathicotonic nervous disturbances; 3, mental upsets of the anxious type, likewise related to sympathicotonia; 4, endocrine disturbances, featured mainly by menstrual disorders, secondarily by disturbances referable to the thyroid gland. The patients complain of cold hands and feet, coupled with hypesthesia and sometimes prickling sensations. The skin may be pale, livid or purplish red. Occasionally the fingers are sausagelike, and the skin of the extremities often shows slight excoriations, and may be thickened. The veins of the distal segment are very often turgid; there may be slight edema or even an erythema induratum. During the periods of circulatory disturbance the radial and dorsalis pedis arteries are almost or quite pulseless, while the brachial and femoral pulsations are not only normal but often even accentuated. The pulse pressure is normal or even abnormally high. Capillaroscopy shows a marked reduction of the arterial blood supply at the extremities, with or without venous stasis. After exposure to hot air, the pulse and capillary circulation are found much improved and the tissues are warmer and show a change of color. The disturbance is thus due to a spasm of the arteries and arterioles, limited to the distal segments. The sympathetic disturbances comprise neuralgic pains in the chest, limbs and head, typically mobile and wandering. Precordial (anginoid) and epigastric (solar plexus) pains, on the other hand, are fixed in location. Headache of the migraine type is frequent, and there are often joint pains, especially in the menopause cases. Other symptoms are anxiety, a tight feeling in the throat, dry mouth, restlessness, slight tremor, and thoracic oppression. Mentally, irritability, anger and anxiety occur during the periods of vascular spasm. That an endocrine disturbance is associated is indicated by the fact that the symptom group appears either at puberty, the menopause, or in conjunction with dysmemorrhea. The symptoms are apt to set in or become worse in the premenstrual period and be relieved when the flow begins. Out of nineteen cases, two had evidences of hyperthyroidism and one, exophthalmos without frank Graves's disease. In six out of seven cases in which the basal metabolism was determined it was found greatly increased during the periods of activity of the symptoms. The syndrome seems related to a disturbance of ovaro-uterine function, with a cyclic character coinciding with the menstrual periods.

Spinal Anesthesia in Cæsarean Section.—A. Brindeau (*Bulletin de l'Académie de Médecine,* March 2, 1926) states that spinal anesthesia possesses certain especially valuable properties for Cæsarean section, having the effect of enhancing contraction and retraction of the uterus while paralyzing the whole of the noncontractile portion of the cervicovulvoperineal canal. In nearly all of 102 cases of Cæsarean section in which the procedure was applied, anesthesia was perfect and the operation carried out under ideal conditions. There were six cases, however, in which the lumbar puncture proved impracticable; in one case the anesthetic failed and in eight cases a little ether had to be added. Aftereffects from the anesthesia were exceptional. The method does not seem to be altogether free from danger in the pregnant woman, however, as there were two deaths in 232 anesthesias, including one in an apparently healthy woman. The preferred anesthetic technic consists of bringing into solution 0.08 to 0.1 gram of powdered procaine directly in the patient's spinal fluid. Spinal anesthesia renders Cæsarean section, especially when suprapubic, much easier. The risk of fatality should be balanced against the advantages of almost complete absence of hemorrhage, a much simpler aftermath and a low morbidity.

Prophylaxis of Thrombosis of the Femoral and Iliac Veins and of Embolism Following Labors and Gynecological Operations.—M. Walthard (*Schweizerische medizinische Wochenschrift,* September 24, 1925) asserts only the slowing of the blood stream can be therapeutically attacked as an etiological factor in thrombosis of the femoral and iliac veins, namely, by the artificial acceleration which is induced by active motion therapy.

At the University Gynecological Clinic in Zurich, the following gymnastic exercises are carried out two to three times daily, beginning from the first day postpartum and after operation in obstetrical and operative cases, respectively, as long as the patients remain in bed:

1. Extension of the arms laterally, first in the lying and then in the sitting posture; flexion and extension of the wrists; flexion and extension of the elbow joints, each ten times.
2. Internal and external rotation of the feet and flexion and extension of the feet, in the dorsal position with the arms firmly held against the body, each ten times.
3. Extension of the arms upward and laterally, first in the lying and then in the sitting postures, five times in every direction.
4. Elevation, flexion, extension and dropping of the legs, first one and then both, in the dorsal position, with the hands holding the head of the bed, each five times.
5. Deep (diaphragmatic) breathing, in the dorsal position with the arms held tightly against the body, five times.
6. Raising the upper part of the body, five times, in the dorsal position, with the hands resting on the hips or on the bed.
7. Rotation of the leg inward and outward, each five times, in the dorsal position, grasping the head of the bed with the hands.

8. Elevation of the small of the back with spreading of the knees, three times, in the dorsal position with the hands resting on the hips and drawing up of the feet to maximal flexion of the knee and hip joints.

9. Elevation of the arms, laterally and upward, with deep inspiration and expiration, five times, first in the lying and then in the sitting position.

These exercises are practised in postpartum and operative cases, in antepartum cases, and by patients awaiting operation. They are contraindicated only in patients who come to the hospital with thromboses and phlebitides. For women having varicosities of the subcutaneous veins the foot of the bed is elevated fifty cm. above the level in the intervals between the exercises.

ENDOCRINOLOGY

Thyroid Function and Dysmenorrhea.—With the aid of metabolism experiments Walther Schmitt (*Zentralblatt für Gynäkologie,* October 31, 1925) was enabled to show that in a large proportion of the patients with dysmenorrhea examined there was a disturbance of thyroid function. Hyperfunction was found twenty-two times and hypofunction seven times among forty cases. In most of the cases enlargement of the thyroid gland was found at the same time. In this material the author was unable to tell whether this was simply a coincidence of disturbed thyroid function and dysmenorrhea or whether an etiological relationship had existed. At any rate such a relationship, in view of the close relationships between the thyroid gland and both the genital organs and the nervous system, is very probable; this is suggested not only by the dysmenorrhea, but also by the fact that associated menstrual disurbances, a diminished fertility and signs of infantilism are frequently observed. In every case the experiments showed that not all cases of dysmenorrhea could be traced to the disease of the thyroid gland, as in some of the cases the thyroid function was unchanged. The truth of the assumption that at least in some of the cases the changed thyroid function produced the dysmenorrheic symptoms can be proved only when it is possible to cure the dysmenorrhea by a suitable action upon the thyroid gland. Only then can we determine whether we can achieve better results with local or thyroid gland treatment, or with a combination of both. It may be possible that in some cases, in which we have heretofore justly assumed the existence of a mechanical cause for the dysmenorrhea and the sterility (angular anteflexion, stenosis of the internal uterine os, and hypoplasia of the uterus), we may produce a functional stimulation of the uterus by influencing the thyroid gland, and thereby cure the mechanical obstruction and the dysmenorrhea.

Metabolic studies will show what cases are suitable for a thyroid gland treatment and in what way this can be accomplished.

Exophthalmic Goitre.—E. Goetsch (*American Journal of Surgery,* Vol. XXXIX, No. 12) maintains that the preoperative use of the x ray in acute cases, with the purpose of reducing the hyperthyroidism, is inadvisable. On the more active gland the inhibitory effect of the x ray can be produced only by the employment of more and larger doses of x ray, and such doses involve direct cellular injury. In a number of cases in which an acute thyroid had been previously treated by x ray, the results after resection were not found to be either as good or as prompt as in the untreated cases.

Iodine should not be given preoperatively unless operation is contemplated at the end of the ten day period. If a patient has thus been treated with iodine, with the usual lull in the disease and is then not operated upon, a period of true crisis follows, after six to eight weeks, with symptoms more severe than before the iodine administration. Again we have noticed that when this relapse following iodine administration has occurred a second period of iodine administration is not followed by the same improvement in symptoms and signs nor by the striking fall in the metabolic rate.

As regards the operation itself, the interval between ligation and excision should be sufficient to allow for the improvement which takes place in four to six weeks and occasionally requires from two to three months. A longer time than this is not advisable because of the increased difficulty of the excision operation due to the marked vascularity resulting from the establishment of collateral circulation in the gland. The author practically never allows the patient to go with ligation alone no matter how much the improvement, because of the tendency to relapse after collateral circulation has been established. The surgeon who operates on the gland nine months or longer after ligation, may find himself in considerable difficulty. It is my custom to do arterial ligation and not polar ligation, the former being sufficient and usually easier. Improvement occurs as a result of the diminished blood supply.

In recent years, on account of occasional relapse following single partial lobectomy, more radical resection of the gland has been practised. When possible three fourths to four fifths of the total gland substance is resected. It should be noted, however, that the ultimate result after single lobectomy, that is after one or two years, may be quite as good as or even better than after the more radical operation. Complete cures very often are obtained when sufficient time has elapsed after single lobectomy, the opposite lobe having reverted to the normal condition again. Such a person appears better and often feels better than the patient who has had the more extensive resection. The latter may show some thickening of tfhe skin, a somewhat dull reaction generally and in some cases a hypothyroidism or even a mild myxedema requiring thyroid therapy for its relief. This never occurs with the unilateral operation. I wish to emphasize that not all patients should, off hand, be submitted to the radical resection operation. It may be perferable to do a second lobectomy on a few patients, who may require it, than submit all the patients to a double resection that is not always needed. This is a point which future ultimate results will have to determine. Complete lobectomy, even if only one sided, is never carried out; a fringe of gland is allowed to remain posteriorly together with the posterior capsule of the gland, for the protection of the parathyroid glands and recurrent laryngeal nerve.

Pituitary Tumors.—Oskar Hirsch (*Wiener klinische Wochenschrift,* January 21, 1926) asserts that heretofore only the acromegalic and adiposogenital clinical forms of tumors of the hypophysis have been given most of the attention, and he therefore emphasizes the ocular form, which he has already described. His report is based on one hundred cases of pituitary tumors verified at operation.

The ocular form is characterized by visual disturbances without any striking change in the patient's habitus. Questioning of the patient almost always elicits a history of disturbances of the function of the sexual glands (impotence or menopause) and a physical examination usually reveals also some of the other symptoms found with pituitary tumors, such as loss of hair in the facial, axillary and pubic regions, disturbances in the secretion of sweat, somnolence, indifference and a low body temperature. The female mammary gland usually contains a secretion. The most important symptom in the disease picture is the disturbance of vision, such as reduction in visual acuity and limitation of the visual field, usually in the form of bitemporal hemianopsia, which is almost pathognomonic. This was found in eighty-four per cent. of the cases. Of equal importance is the presence of a primary atrophy of the optic nerve (eighty-nine per cent. of the cases). The rest of the cases (eleven per cent.) showed choked disc and neuritis. These two symptoms, especially the neuritis, should be considered as pointing to the presence of a pituitary tumor only, when all the other symptoms definitely point to a pituitary tumor.

The author observed thirty cases of acromegaly and he divides them into two forms: the malignant or the classical acromegaly, and the benign form. They are differentiated pathologically by the malignant and benign forms of the tumor, respectively. Clinically, they are differentiated by the visual disturbances.

In the benign form of acromegaly visual disturbances never appear in life; in the malignant form a progressive visual disturbance occurs. The visual disturbances only indicate the nature of the tumor. The positive findings in the benign form include usually a severe grade of hypertrichosis, less frequently genital disturbances, marked activity of the sweat and sebaceous glands, thickening of the skin up to the formation of folds, hypertrophy of the epithelium of the tongue, aside from enlargement of the tongue, marked defects in the dental enamel, disturbances in the growth of the nails, and in one case there was an early bilateral cataract. In the early stages there may be most severe headaches. There may be marked psychic disturbances. The lesion is a

benign adenoma of the anterior lobe of the hypophysis, consisting chiefly of eosinophile cells. True diabetes is found only in a few cases, but an alimentary glycosuria is more common.

The malignant form of acromegaly is called so because it is caused by a progressively growing and, therefore, clinically malignant tumor in contrast to the benign form, which is characterized by a stationary tumor. The characteristic features of the malignant form are the visual disturbances, a masklike change of the face, a thickened and markedly prominent, almost always enormous nose, thickening of the eyelids, enlargement of the lower jaw, a markedly everted lower lip, diastasis of the teeth, thickening of the tongue, pawlike hands and feet, kyphosis of the spine, hypertrophied ribs, etc. Hypertrichosis is rare. Genital disturbances are just as common in this group as in the others. The headaches are usually absent.

The Inevitable Damage Consequent Upon Goitre.—Frederick A. Coller (*Boston Medical and Surgical Journal,* September 17, 1925) says that endemic goitre is composed of colloid and adenomatous elements. In early life the colloid element predominates, after twenty-five the adenoma predominates. These changes are progressive and constant and in time, the length of which is well established, will cause the appearance of symptoms.

Frank hyperthyroidism caused by endemic goitre will be found to increase in frequency from the latter part of the third decade to the fifth and sixth decades when at least a third of the cases will have it.

Definite cardiovascular damage will appear in at least a quarter of those with hyperthyroidism and in a smaller but appreciable number of those with normal metabolic rates.

Endemic goitre is a precancerous lesion with an incidence of malignancy of at least three per cent.

Endemic goitre causes many mental changes of a minor, but disabling nature and in those with a psychopathic inheritance may excite the appearance of some mental abnormalities.

The progressive nature of the goitre pathology and the appearance of symptoms enable us to attack the goitre at a time when medication has ceased to be effective and when the changes begin to menace the health of the patient. The surgical removal of the adenomatous goitre at this time will prevent the appearance of the great morbidity otherwise to be expected.

The removal of adenomatous goitres should be advised on diagnosis in individuals after the age of twenty-five.

Functional Mitral Pseudostenosis in Basedow's Disease.—G. Bickel says (*Presse médicale,* August 29, 1925) that Basedow's disease shows a special predilection for the clinical picture considered pathognomonic of mitral stenosis, and presents it sometimes with surprising clearness in the absence of any valvular lesion. He considers that the appearance in connection with this disease of the physical signs of functional mitral pseudostenosis denotes the passage through an auriculoventricular orifice physiologically narrowed by the reflux of blood marking the close of ventricular diastole, of a stream of blood abnormally intensified by hyperkinetic contraction of the chamber, which is compelled by the increased accumulation of peripheral blood to add to its permanent function as a reservoir that of an auxiliary pump. This view, besides accounting for the rigid restriction of the physical signs of pseudostenosis to the presystolic period, at the same time explans their varying with the cardiac rhythm.

Extraction of a Parathyroid Hormone Which Will Prevent or Control Parathyroid Tetany and Which Regulates the Level of Blood Calcium.—J. B. Collip (*Journal of Biological Chemistry,* March, 1925) has prepared an extract made by acid hydrolysis of the parathyroid glands of the ox by which he is able to control or prevent tetany in parathyroidectomized dogs. Coincident with the clinical improvement following the use of the extract, the blood calcium level was raised or restored to normal. It was possible to give an overdose of the parathyroid preparation, and in such an evtent an abnormally high blood calcium content was found, and along with this blood picture there were associated typical clinical symptoms. The extract may be effective by the oral route of administration, but the best results were obtained by subcutaneous injection.

Action of Insulin in Adrenal Insufficiency.—G. Maranon (*Presse médicale,* December 19, 1925) adduces clinical observations which led him to the conclusion that adrenal insufficiency is associated with a state of unusual sensitiveness to insulin; otherwise harmless doses of this substance produce serious and even fatal effects in patients with Addison's disease. This hypersensitiveness to insulin is not due to the poor general condition of these patients, because it does not occur in other cachectic individuals, even though their blood pressure and blood sugar be low as in the Addisonian cases. The experimentally noted antagonism between adrenalin and insulin permits of the supposition that the reduction of adrenalin secretion in these cases is actually the cause of their hypersensitiveness to insulin. Adrenalin appears to be the physiological remedy for the untoward effects following insulin. In addition to the chemical phenomena, circulatory depression seems to play a part in the pathogenesis of these effects. In either instance the inability of the system to react quickly seems to exert a greater influence than the intensity of the disturbance *per se.* The clinical similarity between the hypoglycemic syndrome following insulin and the sudden grave symptoms presented by some Addisonians in the terminal stage of the disease is of interest, and suggests that a sudden hypoglycemic factor may be operative in the so-called Addisonian encephalopathy. Hypoglycemia is ordinarily present in adrenal insufficiency. Some recent cases of the author showed that in diabetics dying in coma in spite of insulin treatment which had overcome hyperglycemia and acidosis, severe lesions of the adrenals are present. This factor should be taken into account hereafter in cases in which coma appears after the acidosis has been mastered.

Endocrinosympathetic Etiology and Organotherapeutic Treatment of Psoriasis.—R. Carillon holds (*Revue Française d'Endocrinologie,* February, 1926) that psoriasis is a dermatosis appearing in individuals of long-standing constitutional predisposition. Sometimes there exists a psoriatic heredity, but much more frequently it is the sequel of an infectious malady, acute or chronic, tuberculosis and syphilis being most common. It often happens in this constitutional condition that one or more endocrine glands undergo alteration, but not by any means always the same one. Accompanying this, there constantly occurs a disturbance in the tonus of the vegetative nerves, producing a modification of nervous conduction in the sympathetic nerve. This nerve then loses its normal control of nutritive exchange, and impairment of metabolism results in the cells of the epidermis, such that the corneal layer becomes deficient in keratin. Cohesion is imperfect between the cells and the least irritation causes them to desquamate—traumatism or an infectious agent. When success is reached in curing psoriasis by internal medication, the nervous disturbance disappears and keratinization is carried on in the normal way. Treatment of psoriasis must affect both the occasional and the true cause, the former by external measures, the latter by rectifying sympathetic tonus. Extract of thymus gland and insulin are more frequently effective in accomplishing the latter object than are the other endocrine products.

Typhoid and Paratyphoid Thyroiditis: Efficacy of Vaccinotherapy.—A case of thyroiditis appearing without apparent goitre during an attack of typhoid fever with Eberth bacillus was reported by J. Sabrazès, S. M. Flye, and P. Alain (*Comptes Rendus de la Société de Biologie,* 1925, vol. 92). There was a severe inflammatory reaction in the right lobe, and extensive adenopathy extending into the subclavicular fossa. This painful thyroiditis was attended by hyperthyroidism, increased basal metabolism, and positive Goetsch test. Vaccinotherapy had a remarkable effect on the thyroid and lymphatic glands, which diminished rapidly in size, while the general condition of the patient was proportionally improved.

Histophysiology of the Thyroid Gland During the Evolution of a Fracture.—J. Goldner says (*Comptes Rendus de la Société de Biologie,* 1925, vol. 92) the undeniable rôle of the thyroid in relation to fractures consists in causing the appearance of the osteoid tissue in the provisional callus. The organic reactions are hyperfunctional, bringing about the new formation of interfollicular tissue, desquamation, and accumulation of hyperchromatophile colloid. The author is inclined to look on this hyperfunction of the thyroid coincident with the appearance of osteoid tissue as indicative of the participation of this gland in fixing calcium.

CARE REQUIRED BY CHIROPRACTOR TO ASCERTAIN WHETHER AILMENT IS ONE TO WHICH HIS TREATMENT APPLIES

In an action in the Michigan courts, for malpractice against a chiropractic school graduate it appeared that the defendant had not complied with the law relative to registration of drugless healers in the state. Michigan Comp. Laws 1915, §6726. Plaintiff contended that as the defendant had no license to practise in Michigan, and yet held himself out to the public as competent to treat the bodily ailments of those patronizing him, he was practising medicine within the meaning of the Michigan statutes relating thereto, and that his conduct in treating the patient must be tested by the laws and rules applicable to licensed practitioners.

The Michigan Supreme Court held, Janssen v. Mulder, 232 Mich., 183, 205 N. W. 159, that, "while a failure to comply with the registration statute might subject the defendant to a criminal prosecution, such failure, coupled with a showing of treatment given, is not in itself sufficient on which to base a charge of malpractice. To maintain such an action the plaintiff must show that the result complained for was due to negligence or unskillful treatment. While not registered, the defendant was a graduate of a chiropractic school. He but assumed to treat human ailments in accordance with system taught in such school. This fact was well known to plaintiff. The burden was therefore cast upon her to show by competent evidence, not only that his treatment was injurious or not effective, but that the requisite care and skill was not exercised by him in administering it. It necessarily follows that such proof must be made by one engaged in treatment by similar methods to those employed by defendant. With the merits of the several drugless systems of relieving human ailments the courts have no concern. It is sufficient to say that many of our citizens believe in their efficacy and secure the services of those engaged in practising them. The treatment, given by any one of those practitioners, would probably be deemed improper and unskillful when judged by physicians who are taught to treat such ailments by the use of drugs and medicines. The unfairness of permitting the test as to whether a particular treatment was proper or skillful to be determined by one who uses a different method, or follows the teaching of another system, must be manifest.

"This is the first time a malpractice case involving this question has come before this court."

The court cited cases from other states in which questions more or less similar to this were presented, and where the conclusions reached were in harmony with the views above expressed.

The malpractice charged was in the treatment of plaintiff's child, who, according to the testimony of the county coroner who performed an autopsy, died of diphtheria. It was held that if, as the defendant testified, "the class of practitioners to which he belongs does not assume to treat infectious, communicable diseases, they may not be relieved of civil responsibility if they neglect to exercise reasonable care and skill to ascertain whether the person seeking their services is so afflicted;" and that it was incumbent on him to use reasonable care and skill to ascertain whether the patient's ailments were of the class to which his treatment applied and, if not, it was his duty to so advise the child's mother, in order that she might secure the services of one familiar with such ailments.

The court took judicial notice that diphtheria is an infectious, communicable disease. It held that "the plaintiff was entitled to show, if possible, that there is a customary and well known form of treatment used successfully by those of that particular profession who do profess to administer treatment to cure ailments of this nature, and that proper treatment by such a person would probably have afforded relief and saved the life of the child." Judgment for defendant on a directed verdict was therefore reversed and a new trial granted.

ORDER REQUIRING PAYMENT BY EMPLOYER FOR MEDICAL EXPENSES OF OPERATION HELD PROPER

In a claim by a workman for compensation it appeared that after an operation performed by one of the employer's physicians for a compound fracture of the left leg below the knee a sore developed in the left heel which persisted as an open wound for some months. About eighteen months after the injury, after an examination by a physician of the patient's own choosing, it was claimed for the patient that the constant pain he suffered was probably due to a nerve filament being caught in the scar on the heel, and that an operation would relieve it, and such operation was performed after the employer's physicians had refused to do so and declared the operation annecessary. An order of the Industrial Commission under Wis. St. 1923 §102.09, required payment of doctor, hospital and medical bills as a result of the operation, amounting to $587, and an attorney fee of $100. An appeal from a judgment affirming the award the employer contended that the operation was unnecessary. The Wisconsin Supreme Court held, Chain Belt. Co. v. Bayle, 206 N. W. 209, that since there was a dispute among the medical advisers as to the real cause of the constant pain which the claimant underwent after the injury and the necessity for the operation this presented a question of fact for the Industrial Commission, and, having determined that the operation was necessary, and it being conceded that the employer refused to consent to or perform it, this amounted, in substance, to such refusal under the statute as authorized the conclusion and order of the commission. Had the apparent result of the operation been different, the court said, the experiment might well have been decided to be at claimant's own risk and expense.

Whether or not the claimant's refusal to continued to wear a brace fitted to relieve the difficulty with his knee, as directed by the employer's physician, was an unreasonable refusal or neglect on his part under the statute was also held to be a question of fact for the Commission.

DEATH FROM HEAT STROKE NOT COMPENSABLE UNDER KENTUCKY STATUE

The Kentucky Court of Appeals holds, Smith v. Standard Sanitary Mfg. Co., 277 S. W. 806, that where the death of an employee engaged in hauling sand into a foundry with a wheelbarrow was the result of a heat stroke contracted in the course of his employment without trauma, the death was not compensable as an accident under Ky. St. §4880, which expressly provides that personal injury by accident as therein defined "shall not include diseases except where the disease is the natural and direct result of a traumatic injury by accident, nor shall they include the results of a preexisting disease." The Kentucky statute in this respect differs from most if not all other laws, and the court points out that the purpose of this peculiarity "was to exclude from the operation of the statute all occupational diseases not resultant from trauma in order to avoid the confusion with reference thereto under the compensation acts in other jurisdictions."

Failures and Successes in Radiotherapy of Cancer*

HERMAN B. PHILIPS, M.D.
New York

Only too often the casual report of the results of radiotherapy of cancer deals only with the successes; the failures are dismissed as a rule, with very brief comment. As much, and possibly more, can be learned from the analysis of the failures and undoubtedly the greatest amount of good can be gained from a correlated analysis of both failures and successes. The limited time allowed for this presentation prevents any detailed discussion of cases, and for that reason only essential features will be given. The material includes, almost exclusively, cases seen in private practice. Hospital and clinical cases are excluded with few exceptions, as are also a few patients not entirely under my care in private work, so that the series represents only those treated without interference or dictation and with maximum personal attention. A total number of seventy-five cases are included. Treatments were with radium and x ray, of the former, interstitial and pack treatments, of the latter, with voltage varying from 60,000 to 220,000.

Approximately at the end of one year's experience with massive x ray doses given in short periods of time, I concluded that such a method of treatment not only jeopardizes the chances of success, but also decreases in a good many instances the duration of life. Similar conclusions were expressed by other radiotherapists and this method of treatment was abandoned about two years ago. Since that time deep röntgen treatments are extended over long periods of time, and given in small oft repeated doses. Such a technic has of late been described by Morgan (1) of Philadelphia. In this way it is possible to give a greater dose than the patient could otherwise tolerate, eliminate a great deal of röntgen sickness and associated discomforts, and from a comparison with results secured previously and since the inception of this method, to secure unquestionably better results. An additional advantage is the securing of a prolonged saturation period of lethal radiation effects, which is unquestionably desirable in the treatment of malignancy. The advantages of this particular feature of radiotherapy has been emphasized by Pfahler of Philadelphia.

In this analysis the total number of cases of each type will be reported first, the method of treatment briefly outlined, the results described, a criticism of the method, if any, on the basis of results, and additional comment will be expressed in the nature of conclusions from the experiences. I purposely omit theoretical considerations, particularly pertaining to the pathology of cancer, except in so far as it has some practical bearing on the subject presented to you at this time. The presentation is essentially one of practical considerations, with the sole view of bettering the results in this only too hopeless disease. I desire, earnestly, to analyze critically this work with but one point of view, that is, the improvement in results and the prolongation of the patient's life, irrespective of all other considerations. It is desirable at this time to call attention to the fact that special features of malignancy, and its treatment, will be considered. Prominent among these are, 1, the relative value of radiotherapy and radiumtherapy, or a combination of both; 2, the value of prophylactic radiation; 3, the value of postoperative radiation; 4, considerations of dangers of biopsy; 5, evaluation of the relative merits of surgery and radiation; 6, influence of constitutional diseases, if present; 7, general factors, such as age, duration and distribution of malignancy, and other factors well recognized in influencing the outcome in surgical treatment and obtaining also for radiation treatment. It should be stated that no cases are included in this report which were not treated more than six months ago and the series extends back six years since my return to practise after the war.

The individual types of tumors will now be considered.

CARCINOMA OF THE SKIN

Ten epitheliomas were treated, three of them large, rodent ulcers. Treatment was with interstitial radiation and radium packs and intensive x ray over the adjoining lymph nodes. Two of them recurred and were treated again with the production of keratosis and telangiectasia. These recurrences were ultimately electrocoagulated and since that time the patients have been entirely well. All healed with fine cosmetic results. Two have been well over five years.

BUCCAL CARCINOMA

Two cases were treated, one of the tongue without glandular metastases, and the other of the cheek close to the alveolar margin with enlarged cervical lymph nodes. The first of these has been cured over three years, and the other for over two years. The treat-

*Read before the Harlem Medical Society, March 3, 1926.

Copyright, 1926, by A. R. Elliott Publishing Company.

ment was with radium needles, supplemented by intensive x ray crossfiring of the neck.

CARCINOMA OF ESOPHAGUS

Three cases were treated. Two far advanced cases were uninfluenced and in the other the tumor completely disappeared and the patient has been clinically free from symptoms for four years. The patient is still alive and well. The diagnosis in these cases was clinical and röntgenological. I do not believe in subjecting the patient to biopsy, for reasons which will be stated subsequently, and I feel also that all other diagnostic instrumentation should be avoided, if possible. Esophagoscopy in malignancy is veritably a crude type of manipulation even in skilled hands, and I feel it jeopardizes the chances of a cure and should be used only when indispensible. Because of the surgical ineccessibility of this disease, Crile (2), in a recent discourse on the surgical treatment of carcinoma, has expressed the prevalent thought that radium and deep x ray therapy present some basis for hope, especially in the earlier cases. Bowing (3), of Rochester, Minnesota, mentions a three year irradiation cure of carcinoma of the esophagus. Guisez (4) reports a number of three year cures and marked improvement in all of the recent cases treated and is optimistic as to the future, owing to the marked improvement in technic.

CARCINOMA OF THE STOMACH

Two cases were treated, one inoperable and the other postoperative. Palliative results were secured in both but the results were of very short duration. Because of the close proximity of the stomach to and consequent damage of the liver and adrenals, the effects of radiation are not encouraging, although a special technic devised by Hohlfelder (5) was followed in this inoperable case. Nevertheless, only palliative results were secured. Carcinoma of the stomach is still at this time a purely surgical condition.

CARCINOMA OF THE LIVER

Three cases were treated. Two were uninfluenced and in the third case there was considerable retrogression in the size of the tumor with marked improvement in the health of the patient, who finally suffered recurrence and succumbed to the disease. Hyperpyrexia was noticed in two of the cases, preceding the terminus, and in all probability was a result of the radiation effects on the liver.

CARCINOMA OF THE DESCENDING COLON

One case was treated with radium packs, without any results whatsoever.

CARCINOMA OF THE RECTUM

Five cases were treated. Two were temporarily improved with marked shrinkage of the lesions. Two cases were not affected by the treatment and in the last case disappearance of all apparent lesions was secured but it was necessary to produce an intense congestive radiation catarrh to secure results described. Here again Crile (2) has conceded that radiation therapy promises to supplant surgery, for the rectum is readily accessible for the implantation of radiation and portals of entry are available for deep x ray. He recommends colostomy plus radiation.

CARCINOMA OF TONSILS

Two cases were treated with interstitial radium radiation, electrocoagulation and intensive x ray over the cervical nodes. One case was rewarded with success and one failed. The failure was in a diabetic patient and presented also involvement of the cervical glands. She was markedly improved for a period of three months. Her life was prolonged in comfort. The other case has only been observed for six months and is without any recurrence locally or any adenopathy at this time. Further comment is unwarranted, because of the shortness of the period of observation.

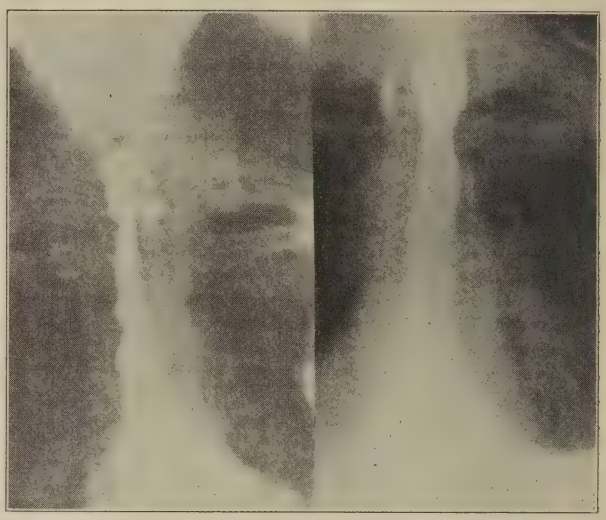

Fig. 1.—Mrs. B., aged fifty-eight, clinical and röntgenological carcinoma of esophagus with large perforating malignant ulcer in upper fifth. Emaciated, cachectic; had lost more than fifty pounds in weight; could only swallow fluids. Illustration on left shows condition before radiation was started. Illustration on right shows condition six months after beginning of treatment. Radium tubes internally in the esophagus and x ray cross firing through the chest was the technic used. Patient regained all of lost weight; experiences no difficulty whatsoever in deglutition; has been perfectly well for over four years and is alive at this time.

HODGKIN'S DISEASE

Two cases were treated successfully, one without any recurrence for three years and the other for over a period of two years.

LYMPHOSARCOMA

Two cases were treated, one with generalized involvement. Complete disappearance of all palpable tumors was accomplished rapidly with complete relief of all symptoms for approximately one and three years. In the former case the patient succumbed prematurely to the disease, apparently from abdominal metastases.

CARCINOMA OF THYROID

Two cases were treated, one with partial symptomatic improvement with fibrous and calcific replacement of most of the gland. The tumor diminished slightly in size, but still is present, large and uncomfortable. When first seen this patient was extremely dyspneic and a tracheotomy seemed necessary at any moment, but this feature disappeared and she has been fairly comfortable for four years and is still alive. In the second case, when originally seen the patient had metastases in the lung and palliative results only were secured for a few months.

CARCINOMA OF THE MEDIASTINUM

One case was treated, but not influenced in the slightest degree by intense x ray crossfire radiation.

CARCINOMA OF LUNG

Four cases were treated. In one advanced and hopeless case a metastatic supraclavicular node was

FIG. 2.—Miss G., aged thirty-two, carcinoma of breast, metastases in second, third and fourth right ribs anteriorly, along with sternal nodules and supraclavicular nodes, which appeared a few months after radical operation. Radiation with radium needles and intensive x ray cross firing resulted in complete disappearance of all evidences of disease for approximately three years, when lumbar spine and internal metastases developed and proved to be fatal. Figure on left shows destruction and absorption of the anterior portion of the second, third and fourth ribs. Figure on right shows bone regeneration of the second, third and fourth ribs clear to costocartilaginous junction.

removed for biopsy. In less than two weeks' time, after the biopsy, mitotic cells were recovered in the patient's urine. In about six weeks' time he died of general metastases. Treated in parallel with this case was another of neoplasm of the lung, with almost identical distribution which was radiated intensively by x ray and not biopsied. The tumor and all metastases disappeared with complete freedom of all manifestations of the disease over a year and a half, when fatal recurrences occurred. The third case, in a man over seventy-four years of age with

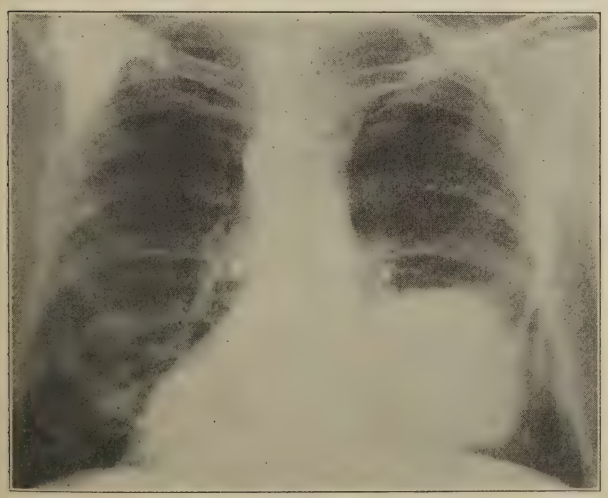

FIG. 3.—Mr. S., aged seventy-four, metastatic malignant carcinoma of right lung with hemoptosis, cough and dyspnea, before radiation.

metastatic carcinoma of the lung, was under observation for over six months' time with almost complete retrogression of the tumor and was symptom free during this time. Another case, with metastases from carcinoma of the thyroid, was improved with moderate shrinkage of the tumor and stoppage of hemoptysis.

CARCINOMA OF THE BREAST

Twenty-five cases were treated. Of this number three received preoperative and postoperative radiation. All of these patients died, after two to three years' freedom from the disease, but two of them were in a far advanced and hopeless stage when seen. Postoperative radiation was carried out in all of these cases and in this number six patients are dead and nineteen alive and well without any signs of recurrence. As regards metastases, seven cases were treated. All patients were improved to the extent of complete disappearance of the lesions for a period varying from six months to four years. To my knowledge only one patient is alive at this time. Of

FIG. 4.—After three months' radiation with intensive short wave technic, symptoms completely disappeared and tumor almost completely resolved. Patient died from primary intraabdominal focus three and a half months later.

this number two very strikingly successful temporary results were secured, one in metastases of the upper end of the femur and the other in the ribs.

Two unusual experiences were encountered in this study, to which attention should be called. In one instance carcinoma developed in the remaining breast of a woman who was being treated for recurrent nodes over the sternum. Notwithstanding homogeneous radiation being given over the entire chest wall and the fact that the sternum nodule disappeared, the malignancy of the remaining breast developed insidiously during the course of treatment. The other instance is quite similar. Homogeneous radiation was given over the breast and axillary region of a young woman (inoperable) with a very malignant adenocarcinoma with almost complete disappearance of the axillary metastases, while a violent uncontrollable growth progressed throughout the breast.

In two inoperable cases which were treated only with radiation, one patient had complete disappearance of metastatic nodule in the remaining breast and

the other had the initial lesion, the size of a walnut, shrink to a very hard fibrous mass (eight months' observation). It is unfortunate that my series has no parallel nonradiated surgically treated cases for comparative purposes, nevertheless, a few conclusions are justifiable from the analysis of this small series. Prophylactic radiation on a basis of experimental animal research should be followed where possible, notwithstanding the failures of the three cases I reported, which were far advanced and hopeless. Murphy has shown that transplanted tumors will not grow in radiated sites. Some experiments reported by Schreiner and Simpson (6) are worthy of record at this time. Malignant tissue which was radiated and then inserted into the body would not grow, nor would nonradiated tissue planted in a radiated site.

Postoperative treatment in my series has resulted in approximately sixty per cent. freedom from recurrence over a prolonged period of observation. Lee and Herendeen (7) assert, on a basis of analysis of ninety-two breast cases from various hospitals and surgeons, that preoperative and postoperative radiation is justifiable. In the cases treated with surgery alone twenty-four per cent. of the patients lived three years; of those operated upon and receiving postoperative radiation thirty-nine per cent. lived three years, and of those patients who received preoperative and postoperative radiation fifty-two per cent. lived three years. Pfahler's (8) results in all cases, early and late, operable and advanced, inoperable and recurrent, were fifty per cent. of the patients alive for three years and twenty-seven per cent. alive five years and more. In the postoperative group without glandular involvement eighty-one per cent. were alive for three years and seventy-seven per cent. alive for five years and more. In the postoperative group with glandular involvement, fifty-six per cent. were alive for three years and thirty-eight per cent. alive for five years and more. The treatment of metastases when discreet and not generalized, is satisfactory with frequent complete disappearance of the lesions and accompanying symptoms. When the metastases are too disseminated and generalized it is futile to attempt radiation, but a few metastatic foci can be handled successfully as a rule. However, the result is not permanent in a great number of cases, but merely a palliative procedure. I have no reason for feeling that radiation is harmful in any way and for that reason recommend it preoperatively and postoperatively and earnestly advise radiation for metastases when not too disseminated.

CARCINOMA OF THE OVARY

Three cases of this character were treated. One patient in a hopeless inoperable condition, subjected to exploratory laparotomy, was radiated, with complete disappearance of all clinical symptoms of tumor for a period of one and a half years, when the condition returned and proved fatal. Another patient was radiated postoperatively, where apparent complete removal of the tumor was accomplished with complete freedom from symptoms for over three years. Radiation in this instance is of questionable value, inasmuch as the entire disease may have been removed. In a third case with slight ascites and generalized carcinomatosis of the abdominal cavity the patient was not benefited.

CARCINOMA OF THE UTERUS

Two failures were recorded in the treatment of carcinoma of the body of the uterus, which can be attributed to the extreme obesity of the patient and inaccessibility of the tumor. These patients were ultimately subjected to hysterectomy, although poor operative risks, and the futility of attempting to treat extremely obese women was demonstrated in the pathological specimens. Although in both of these cases the hemorrhage ceased and the growth of the tumors was arrested apparently, for periods of over two years, ultimately the uteri had to be removed. Combined intrauterine radium application and intensive x ray crossfire was used without permanent success.

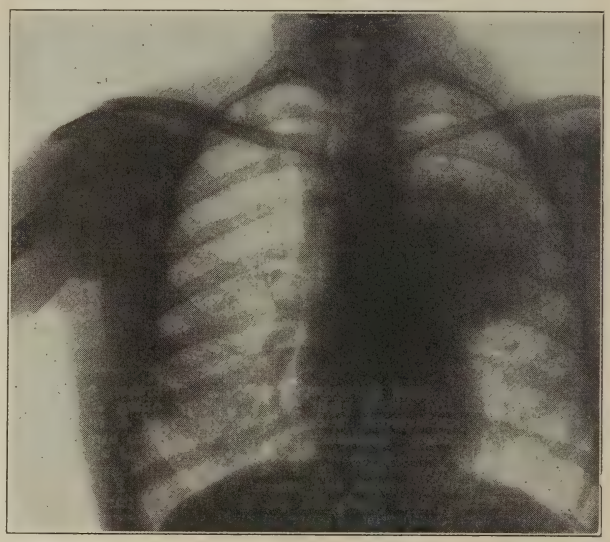

Fig. 5.—Mrs. R., aged twenty-six, primary neoplasm of lung with supraclavicular and mediastinal and axillary adenopathy. Cachectic, anemic, underweight, night sweats and marked dyspnea. Fig. 5, ectic, anemic, underweight, night sweats and marked dyspnea before radiation.

CARCINOMA OF THE CERVIX

As regards carcinoma of the cervix, the results are reversed, because, unquestionably, of the accessibility of the tumor. Treatments comprise radium needling and tubes and intensive x ray crossfiring. Three cases, recurrences after operation, were radiated with gratifying palliative results and complete disappearance of all evidences of the tumor from two months to over one year. However, all the patients in this group have died. In six other patients not operated on, two with extensions of the tumor over the vaginal vault and one with a perforation of the bladder, the results were ideal with complete disappearance of all symptoms, from one year to four years.

CONCLUSIONS

The conclusions from this group of uterine tumors corresponds generally with results published elsewhere. Carcinoma of the uterus is primarily a surgical condition and carcinoma of the cervix is primarily a radiation problem. The less of surgery in carcinoma of the cervix, the better the outcome. Crile (2) has expressed himself concisely on this subject and states that "We are turning over all our cases for radium and deep x ray therapy in cases of carcinoma of the cervix. However, we still advocate vaginal hysterectomy for carcinoma of the fundus."

CARCINOMA OF THE URINARY TRACT

One case of hypernephroma was treated with x ray and radium packs. The patient was improved temporarily with slight shrinkage of the tumor and loss of pain, but succumbed ultimately to the disease. One case of carcinoma of the bladder with extensive involvement was treated with combined radium, interstitial radiation and intensive x ray crossfire. Intense radiation cystitis occurred, but the tumor completely disappeared for over a period of one and a half years. The patient is alive and well at this time.

FIBROSARCOMA

Two cases were treated, one of the hand and the other of the foot, with marked temporary retrogression of the tumor, but with ultimate fatal outcome. Treatment was with combined radium, interstitial radiation and intensive x ray crossfire.

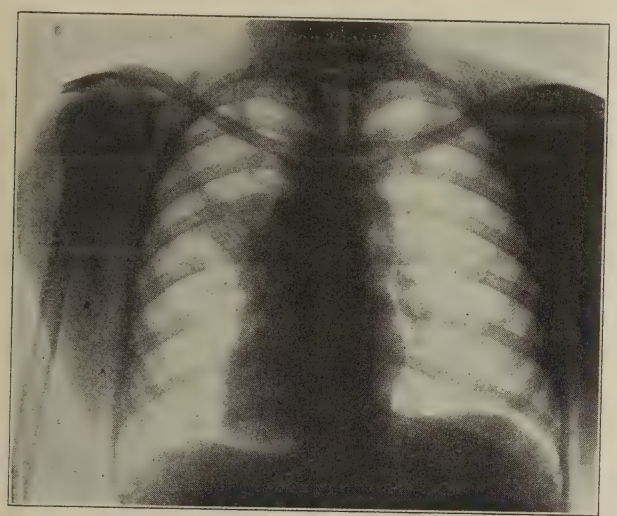

FIG. 6.—After intensive x ray cross firing radiation; about three months later complete clinical cure and disappearance of all röntgenological evidences of tumor. Patient free from symptoms for one and a half years, when fatal recurrences supervened, which did not respond to further treatment.

CANCER OF THE BONE

Four cases of osteogenic sarcoma of the bone, three of the long bones and one of the scapula, were treated with intensive x ray radiation, interstitial radiation and radium packs, without affecting the outcome in the slightest degree. One case of Ewing tumor of the femur was treated with complete disappearance of all symptoms for approximately one year, when a recurrence occurred with a second lesion in the humerus. Attention is called to the disappearance of all subjective and objective symptoms, including röntgenological evidences of the tumor, in the humerus, when the recurrence in the femur was radiated. Such phenomena have been observed in the radiation of skin diseases, warts and in lymphosarcoma, but according to recent comment on this case by Dr. Ewing, this phenomenon has never been observed before in this condition. Four cases of metastatic bone carcinoma were treated. One case in particular with extensive involvement of the ribs, was treated with interstitial radium radiation, radium packs and heavy x ray crossfiring, the other cases by intensive x ray crossfire or radium packs. The disappearance of these tumors over periods of from one to three years was secured.

In reviewing the preceding, one is impressed by the fact that while palliative results is the rule with radiation of tumors, permanence of results is deplorably infrequent. As Dr. Mayo has said, "Radiation therapy is at its best a triumph and a despair. It often does so much good that the patient and family begin to look for cure, failure is the result, and radiation therapy is unjustly brought into disrepute for a meritorious performance." It has been my privilege in the last few years to have at one time over twenty instances of most gratifying clinical cures of otherwise hopeless malignancy, and to see these patients, with a few exceptins, fall by the wayside one by one, as a result of recurrences which did not yield to further treatment. The failure of permanency in the results of radiation therapy, in the majority of cases, detracts in no way from the conceded value of this method of treatment in prolonging life in comfort, and accomplishing in a good many instances almost the impossible and incredible, far beyond the possibilities of any other method of treatment. It is apparent also that the greatest number of successes obtained in these cases is due to the peculiar susceptibility of the tumor; in other words, our successes are fundamentally based on the good fortune of accessibility of the type of malignancy to radiation or to the accessibility of the tumor, in other words, our successes are fundamentally based on the good fortune of accessibility and not completely upon the inherent uniformly successful qualities of our therapeutic agent. It is further apparent that more permanency and the greatest good can be obtained in the treatment of malignancy by a combination of surgery and radiation. Radiation, by lowering the virulence of the malignancy and surgery by its total enucleation where possible.

The well known fact, expressed by Judd (9) of the Mayo Clinic, to the effect that "Certain cases of cancer seem to be hopeless from the beginning, and surgery or any other method of treatment does not influence the progress of the neoplasm whatsoever, nevertheless, in the great majority of cases, the course can be influenced by radiation or surgery, or both." A number of factors favorably influence the course of the disease irrespective of the character of the treatment, and these are: the duration of the condition, its location and clinical virulence, the age and health of the patient, the presence or absence of systemic disease, accessibility of the tumor, the success and skill in the technic of treatment, and the selection of the proper form of treatment. The last named question deserves special comment, inasmuch as sufficient records have accumulated to make the fact conceded by surgeons as well as radiotherapists, that certain types of malignancy should no longer be treated by surgery. To elucidate further, it is conceded generally that malignancy of the skin, esophagus, rectum, uterine cervix, and lymph adenopathy including Hodgkin's disease, are best treated by radiation, whereas it is conceded by the foremost surgeons of the country that in all other cancers, in almost all instances, surgery should be combined with radiation to get the best results. The choice of radiation technic depends upon the experience and skill of the radiotherapist and in a great many instances combined radium and x ray treatments have demonstrated greater efficacy than either agent alone. Dant-

witz (10) has shown that combinations of radium and x ray have been more beneficial than x ray alone.

The causes of failures in radiotherapy are in common with failures in surgery. The treatment of cancer is postponed until the condition is too disseminated and the patient too weakened by the disease to do justice to the condition or the method of treatment. As far as the radiation treatment is concerned, it is possible that a good many of the failures are due to over treatment, and in other instances to under treatment. The effect of radiation is, in my mind, directly proportional to the amount of radiation expended. Small doses will stimulate, greater doses will depress, the proper dose will destroy cancer tissue and exceeding this proper dose will lower the tissue resistance so that the effect will be equivalent to one of stimulation and the dose used must be so gauged as to have the desired effect. The factor of general resistance to radiation must also be considered, because unquestionably the use of little discretion in giving huge doses of x ray radiation without keeping in mind the condition of the individual, contributes to a great number of failures. The use of tonics, transfusions, rest periods, small dose technic are all important factors in preventing to some extent the failures in treatment. The importance of consistent "follow up" in radiation therapy cannot be emphasized sufficiently and no less than four cases of premature death were recorded in my series from neglect on the part of the patient, in this most important phase of the treatment. Examinations at frequent intervals and education of patients to enable them to detect early unfavorable symptoms of recurrence are absolutely essential.

The treatment of systemic conditions, such as nephritis and diabetes, secondary anemia, etc., must be given proper consideration and attention. The use of a divided small dose technic mentioned previously, frequently makes it possible to treat a patient and produce desirable and worthwhile palliative results in otherwise hopeless conditions. The most essential feature of all is one which cannot be dwelt upon sufficiently at all times, namely, the proper education of the layman so that malignancy will be recognized early and the case referred to the proper channels before the condition is hopeless. It is also desirable to educate the general practitioner so that he can direct his patient along the right channels for the proper treatment without additional delay. The tragedy that frequently confronts the radiotherapist is a patient who has not only been guilty of neglecting herself or himself to the extent of permitting a hopeless condition to develop to such a stage that any treatment would be undertaken with reluctance, but frequently cases are called to our attention where obviously the wrong treatments have been instituted and a patient been made to suffer mutilating operations needlessly or extensive and damaging radiation equally needlessly. The happy medium of a consultant for the general practitioner is a clinical pathologist, if I may use such a term, who knows the limitations as well as the merits of the different methods of treatment of malignancy and will impartially advise the general practitioner what course his patient should take. The question of surgery versus radiation must necessarily be based on, primarily, the question of accessibility and distribution of the malignancy, as well as the susceptibility of the condition to radiation; and the existing consensus of opinion as to the preferred method of treatment based on statistical surveys. Combination of surgery and radiation unquestionably will give the best results in the future and it is very probable that the present high mortality in gastrointestinal malignancy will be much lowered, when an intimate cooperation is established between radiotherapists and surgeons, so that when any laparotomy is performed the radiotherapist can be at hand with his needles or radium seeds, to take advantage of the open abdomen, and a much neglected opportunity will be afforded of applying this efficient method of interstitial radiation in otherwise hopeless conditions. All will concede the preference for the complete surgical removal of a focus of malignancy whether radiated or not. However, elaborate microscopic studies and clinical observations have demonstrated the futility of hoping for a complete enucleation of malignancy, except in unusual cases, and the next best procedure is a faithful application of radio therapy alone or combined with surgery.

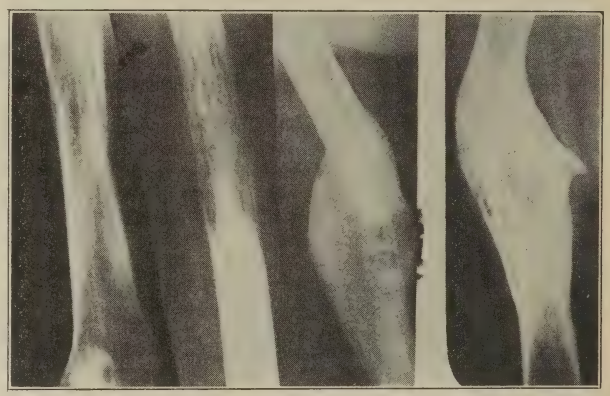

Fig. 7.—Mrs. C., aged twenty-two, Ewing tumor (primary endothelioma) of femur. Sustained pathological fracture day following first x rays. Markedly deformed fractured femur radiated with radium packs and several rounds of deep x ray, voltage varying from 140 K.V. to 200 K.V. Badly deformed pathological fracture united with dense bone proliferation and disappearance of all röntgenological evidences of tumor. Fatal central nervous system involvement about fifteen months after apparent cure of femur lesion. Slight activity in femur lesion at the end of one year, which disappeared after further radiation. (See text under carcinoma of bone.)

This important discussion of practical considerations of malignancy cannot be concluded without some elaboration on the question of the dangers of biopsy. I cannot express the question to you more forcibly than to quote several passages from a recent article by Dr. Ewing (11) on this subject. He "decries the importance placed on a simple report of cancer or sarcoma and emphasizes the necessity for a knowledge of clinical features of the case and not merely histological reports. The cancer surgeon should become highly proficient in the recognition of cancer by sight and touch. No aid from frozen sections can replace this capacity. Röntgenology has greatly enlarged the opportunity for the study of gross anatomy of tumors and should correspondingly diminish the indications for biopsies and exploratory operations. In the field of bone tumors and several other departments it has been an indispensable aid in diagnosis. There are comparatively few bone tumors that cannot be somewhat accurately classed by means of röntgenography and clinical findings. I have often

found that conclusions drawn from röntgenography lead to rather more serviceable results than the study of fragments of tumor tissues taken under difficulties. Biopsy is a method that renders great service in the recognition of tumors but is one that should be practised with the greatest caution. The incision of encapsulated malignant tumors growing under pressure is nearly always harmful and may be disastrous. The therapeutic test by radiation is generally far better and safer. The incision of bone tumors for diagnosis is one of the last steps to be taken, for such incisions stimulate growth by release of pressure, lead to infection, or uncontrollable hemorrhage and moreover the portion of tissue fails to yield a satisfactory conclusion or even leads to errors that might have been avoided by other methods of study. The results of radiation therapy have revealed some interesting data, which may be useful in diagnosis. The susceptibility of giant cell tumors of bone, cellular myeloma and round cell tumors offer a means of differential diagnosis. The response of lymphosarcomas which melt down rapidly under radiation and Hodgkin's disease granulomas which are more resistant, is so characteristic as to be valuable as diagnostic data. Areas of chronic mastitis become swollen and indurated under radiation while cancerous masses gradually recede leaving very hard cicatrices." Other similar information of differential diagnostic value, based on radiation susceptibility are enumerated, but time does not permit their inclusion in this presentation. The dangers of biopsy are apparent in the small series of cases of cervical cancer, which I am reporting. The best results were obtained in those cases not subjected to any operative procedure. Heyman (12) of Stockholm, in a review of a very large series of cases came to the conclusion that biopsies impaired the tendency to heal and favored dissemination of the tumor and unquestionably contributed to failures in the radiotherapy of cancer.

CONCLUSIONS

1. The selection of the method of treatment in malignancy is determined by the accessibility to radiation and surgery and susceptibility of the tumor to radiation.

2. The choice must also be made on a basis of statistical reviews of results of surgical and radiation methods of treatment of the particular type of tumor.

3. Certain types of malignancies are unquestionably treated better by radiation alone, others by surgery alone and a third class by a combination of both. These have been outlined in the body of the article.

4. The success of radiation therapy depends upon early recognition and treatment of the condition, accessibility and radiation susceptibility. Tonic and supportive treatment is indispensible. The small oft repeated dose technic appears preferable to massive doses in a short period of time.

5. Palliative results can be secured in a great majority of cases, and should be attempted with few exceptions. My series includes at least fifteen inoperable and hopeless cases whose lives were prolonged from six months to four years or more, in comfort, the individuals being restored to usual working capacity. Of this number three present clinical cures of over three years' time.

6. A more intimate combination of radiation and surgery will probably improve results in the treatment of cancer of the gastrointestinal tract.

7. Biopsy, manipulation and instrumentation of tumors are dangerous and should be avoided.

Acute Pericarditis

HERMAN ELWYN, M.D.
New York

(*Concluded from page* 9)

When the presence of a pericarditis is discovered in an individual suffering from active pulmonary tuberculosis it may be assumed that the pericarditis is also tuberculous, although this is not necessarily so. When a hemorrhagic fluid is obtained by aspiration of the pericardium in such an individual this is very significant. Tubercle bacilli are rarely found in the exudate, but inoculation in a guineapig usually gives a positive result. It must be kept in mind that tuberculous pericarditis may occur as a complication of genitourinary tuberculosis. In a case of advanced renal tuberculosis a pericardial friction sound was discovered on routine examination, which persisted for six weeks until death. Tuberculous pericarditis was found at the autopsy.

The course of tuberculous pericarditis is usually a chronic one lasting from four to eight months and terminating either in death or in the formation of an adherent pericardium. When the latter occurs the case presents clinically the consequences of an obliteration of the pericardium. With these we are not concerned here. The friction sound is frequently heard for a long period. Schrötter mentions a case in which the friction sound was heard for four months.

AS A COMPLICATION OF PNEUMONIA

The frequency with which pericarditis occurs in the course of lobar pneumonia differs considerably in the reports from the various clinics. Osler (24) found it thirty-five times among 658 cases of pneumonia, or 5.3 per cent. Fraenkel (25) found it in 0.9 per cent. of over 700 cases. Of Waller's eighty-three cases of pericarditis nine were due to pneumonia. Among the 427 cases of lobar pneumonia which I had occasion to study at Camp Greene, North Carolina, in 1918, pericarditis occurred eight times, or 1.8 per cent. (26). Three of these cases, in which no evidence of fluid could be detected, but in which the friction sound was distinctly heard, recovered. In the rest the exudate was hemorrhagic or purulent. Purulent pericarditis, although not common, is usually

a fatal complication in lobar pneumonia. The pneumococcus, streptococcus, or staphylococcus may be found in the exudate. In the cases which I reported from Camp Greene the streptococcus was found, although the pneumonia was due to a pneumococcus.

The clinical recognition of the presence of pericarditis in the course of lobar pneumonia is always difficult and at times impossible. Any pain which is felt by the patient is either overshadowed by pain at the site of the pneumonia or it is assumed to be pleuritic in origin. Usually there is no pain. A daily routine examination of the heart will result in the discovery of a pericardial friction sound when this is present. Just as frequently such a sound is not heard although an exudate is found postmortem. When the pericardial cavity is filled with a fluid exudate the evidence on percussion may be quite definite. It is astonishing, however, how large a quantity of pus, even up to two litres, may be found in the pericardium at autopsy without its presence having been suspected. Perhaps the reason for this may be found in the failure of percussion to be of any help in some of these cases. Anteriorly the heart dullness may merge into pneumonic dullness, and similarly, dullness posteriorly over the left lower lobe is either due to the pneumonia or ascribed to the presence of fluid in the pleural cavity.

Auscultation is frequently of no help. It seems that the heart sounds can be propagated undiminished even through a large layer of pus. When the presence of an exudate in the pericardium is definitely suspected in the course of a pneumonia aspiration is indicated to determine whether pus is present or not. I remember a case of lobar pneumonia which was carefully studied by the attending physician and his staff and then presented to an assembled class of students, without the presence of a pericarditis having been suspected. The patient died about twelve hours later and more than a pint of purulent exudate was found in the pericardium at the autopsy.

IN UREMIA

Acute pericarditis is a frequent occurrence in true chronic uremia. The frequency with which acute pericarditis occurs in chronic uremia is not at all evident from published statistical tables, especially as most of these have been published before the days of proper methods in blood chemistry. In my experience pericarditis occurs in the greater number of cases of chronic glomerulonephritis in the end stage. The exudate is either fibrinous or serofibrinous. The amount of fluid is usually not large, about 50 to 200 c. c., although occasionally larger quantities, even up to 1,000 c. c., are met with. The exudate is rarely hemorrhagic. The cause of the pericarditis in chronic uremia has been the subject of frequent investigations and a good deal of discussion. The exudate has been found to be sterile by Banti and others, although some investigators have found the pneumococcus and the colon bacillus in some cases. In these cases the organism is probably a secondary invader.

Acute pericarditis in chronic uremia does not occur until renal insufficiency is far advanced. The total nonprotein nitrogen in the blood is found to be above 100 mgm. per 100 c. c., and usually in the neighborhood of 150 mgm. or higher. When pericarditis occurs with the figures for the nonprotein nitrogen below 100 mgm. per 100 c. c. of blood, the cause of the pericarditis must be sought elsewhere than in uremia. In many such cases in elderly people with high blood pressure it is due to myocardial infarction. When it occurs in chronic uremia it is accompanied by the other symptoms, nervous, visceral, constitutional, of chronic uremia. The main symptoms are: fatigue, drowsiness, muscular twitching, nausea and vomiting, irregular breathing or the Kussmaul type of breathing, mental symptoms, pallor, anemia, a urinous odor from the mouth, diminution in the output of urine, fixation of the specific gravity of the urine, albuminuric retinitis, and an increase in the blood of the nonprotein nitrogenous substances, urea, uric acid, and creatinine. The blood pressure is increased, or having been previously increased, has fallen to apparently normal figures.

The urea constitutes the greater part of the nonprotein nitrogenous substances in the blood. When retained in the blood stream to a sufficient amount there is a vicarious attempt to excrete the urea by the gastrointestinal tract, the salivary glands, and the skin. All the tissues in the body become saturated with urea. This saturation which affects the serous membranes also results in the excretion of urea by the serous cells into the serous fluid where it is found in as high a concentration as in the blood. The presence of urea in the serous fluid of the pericardium is possibly the cause of an irritation of the serous layer with the formation of an acute pericarditis. Any organisms found are probably secondary invaders.

Clinically, pericarditis in chronic uremia manifests itself by the friction sound. Precordial pain is present at times, but more often absent. The amount of fluid is rarely of such an extent as to give evidence on percussion. Frequently the friction sound is only heard for a few days, in other cases for many weeks. The importance of recognizing the presence of pericarditis in chronic uremia is in the fact that it gives clinical evidence that the tissues are saturated with the waste products of metabolism. Because of this the presence of a pericarditis gives us a clue as to the nearness of the fatal outcome. Cases of chronic uremia seldom survive longer than three months after the appearance of the pericardial friction sound. More often the fatal outcome is much sooner.

IN MYOCARDIAL INFARCTION

The diagnostic importance of a pericardial friction sound following thrombosis of a branch of the coronary arteries has been definitely recognized since Sternberg's publication in 1914 (27). Thrombosis of a branch of the coronary arteries, if not immediately fatal, is followed by an infarct of the heart muscle. When the infarct is sufficiently extensive to reach the surface of the heart a pericarditis occurs over the infarcted area with the deposit of fibrin, sometimes with an increase in the amount of the pericardial fluid which may at times be bloody.

The clinical picture is characteristic. The thrombosis is immediately followed by a sudden excruciating pain in the sternal region or in the epigastrium, radiating into the neck, the left shoulder, the arm and forearm, or both forearms. The pain has all the variations and radiations of angina pectoris, but at times is strictly localized. It is continuous for hours and even days. It is accompanied by marked dyspnea

and orthopnea, and in this it differs characteristically from an ordinary attack of angina pectoric in which the patient usually holds his breath for fear of increasing the pain. The dyspnea is due to the sudden myocardial insufficiency and to the pulmonary edema. The face has an anxious expression and has a pale ashy gray pallor. The pulse is rapid, frequently irregular, soft and thready. The systolic blood pressure falls but the diastolic remains as before the attack, and the pulse pressure may be only 15 to 20 mm. of mercury.

When the area of cardiac softening is at the anterior part of the heart a pericardial friction sound becomes audible within twelve to twenty-four hours. It is often of short duration lasting a few days only; in other cases it lasts for weeks. The myocardial infarction is followed by a low grade fever and a polymorphonuclear leucocytosis. The electrocardiographic changes characteristic of this condition have been studied by Herrick, Smith, Pardee, Oppenheimer and Rothschild, and others. Especially characteristic of coronary artery closure seems to be a change in the R and T waves, and "the katacrotic limb of R may become practically continuous with the peak of T, thus forming an almost monphasic curve" (Oppenheimer and Rothschild), (28). Other changes in the Q R S complex are usually found.

This is the picture of the clinically severe cases. Other cases occur, however, with very little pain and dyspnea, and in which the most characteristic manifestation is the localized pericardial friction sound. In the last sixteen months I have had occasion to observe four cases, three males and one female. All four cases were above fifty years of age, and gave a history of high blood pressure for many years with recent attacks of angina pectoris. These cases were admitted with moderate persistent pain in the lower sternal region following an attack of angina pectoris. Each of these cases presented a localized area of pericarditis which persisted for about one to four weeks. After the first few days the pain disappeared entirely, the systolic blood pressure, which was low on admission, rose, and only the pericardial friction sound remained. All four cases recovered completely. The finding of the pericardial friction sound is, therefore, especially valuable in those cases which do not present the severe clinical picture.

IN TUMOR OF THE PERICARDIUM

Tumor of the pericardium is a rare occurrence. Occasionally, however, a persistent pericardial effusion is observed clinically for which no cause can be found, and at autopsy a tumor mass is found in the pericardium. The effusion is usually hemorrhagic. I have had occasion to observe two such cases. In one case, that of a man of middle age with signs of pericardial effusion, death occurred suddenly. On autopsy the pericardium was distended with a hemorrhagic fluid and small papillary tumor masses were found in the upper part. The other case was that of a man of fifty years with metastatic carcinoma widely disseminated throughout both lungs. There was flatness on percussion over the left base and axilla, and I aspirated what I thought to be the left pleural cavity and removed 800 c. c. of a hemorrhagic fluid. Death occurred in about twenty-four hours. At the autopsy both pleural cavities were found to be completely obliterated and the metastatic nodules so densely packed as to leave hardly any sound lung tissue. The pericardial cavity was filled with a hemorrhagic fluid, but no tumor masses were found in the pericardium. I had evidently aspirated the pericardial cavity.

RARER FORMS OF ACUTE PERICARDITIS

The rare forms have been mentioned at the beginning of this discussion. They are usually dominated by the clinical picture of the original disease. Especially is pericarditis likely to occur in streptococcus septicemia. That streptococcus pericarditis is not always a fatal disease may be seen from the following case observed in the base hospital at Camp Greene during the period of the war. A young man of twenty-one years developed an acute streptococcus empyema of the right pleural cavity. This was drained. He then developed a localized collection of pus in the anterior part of the right chest, which was also drained. Soon after a pericardial friction sound was heard and this was followed by the signs of pericardial effusion. This was aspirated and 400 c. c. of a slightly hemorrhagic fluid removed which proved to contain a pure culture of streptococcus. The fluid reaccumulated in the pericardium and a similar quantity was again removed. The second fluid also contained streptococci. Although a slight amount of fluid reaccumulated it was not necessary to resort to aspiration, and the patient made a complete recovery from the pericarditis and the empyema.

A case of pericarditis which I had occasion to observe last year was that of a woman thirty-nine years of age who was admitted to the Gouverneur Hospital with follicular tonsillitis and a history of cough for three days. Her temperature on admission was 104.8, pulse 120, respiration 30. She presented a rash on her face in a butterfly arrangement, which was diagnosed by the dermatologists as erysipelas perstans faciei. The tonsillitis quickly improved, but seven days after admission she developed precordial pain and on examination a pericardial friction sound was heard. This friction sound persisted during her stay in the hospital of about six weeks. She ran an irregular febrile course with a moderate leucocytosis. Her lungs were negative on physical examination and by x ray. The urine was negative. She left the hospital against advice, while the fever and the pericardial friction sound were still present.

This case of pericarditis is difficult to classify. There was no evidence of rheumatic fever, of tuberculosis, of myocardial infarction, or uremia, and of pneumonia, nor was there any other recognizable cause for the pericarditis. It is quite possible that this case belongs to the group of valvular and mural endocarditis recently described by Libman and Sacks (29), in which pericarditis is of frequent occurrence.

SOME DIAGNOSTIC CONSIDERATIONS

At times the primary disease which is responsible for the presence of an acute pericarditis is not at all obvious. In such cases there are some considerations which may help us to determine what this primary disease is. In children and young people rheumatic affection of the heart is the chief causative factor. In persons past middle age coronary obstruction followed by myocardial infarction is the chief cause.

Where uremia is suspected, the blood chemistry will determine the correctness of the diagnosis. Primary tuberculosis of the pericardium is rare and so are tumors.

In some cases the determination of the character of the fluid exudate is of importance. This is the case in the pericarditis of pneumonia which is frequently purulent, that of septic infections, when the pericarditis has extended from a contiguous suppurative focus, and sometimes in tuberculous pericarditis. In such cases aspiration of the pericardium is indicated. It is hardly ever indicated in rheumatic pericarditis, and practically never in that of uremia and that of myocardial infarction. A hemorrhagic fluid which quickly reaccumulates after repeated aspirations is very suggestive of the presence of a tumor.

TREATMENT

The great clinicians of the first half of the nineteenth century all had a strong belief in the efficacy, in acute pericarditis, of mercury which they gave in large doses, and of venesection and the application of leeches. Happily modern medicine has gotten away from these forms of treatment. For this we are especially indebted to Skoda who demonstrated their uselessness.

In all forms of pericarditis with the exception of the purulent, the tendency for the inflammation is to subside and for the exudate to be absorbed. Treatment should be directed, therefore, first to the primary disease; secondly, towards lessening the work of the heart by rest; and thirdly, toward alleviating any annoying symptom.

The treatment of the various primary diseases needs no discussion here. In acute rheumatic fever, the administration of the salicylates should be continued, although this has probably no effect on the pericarditis.

Rest in bed is of course a fundamental rule. This should be complete. The patient should move as little as possible and should not leave the bed for urination or defecation. The half sitting posture is usually preferred by the patient. The diet should be restricted, semisolid, or liquid when the temperature is high.

Pain is frequently relieved by the application of an ice bag over the region of the heart for short periods of time. The ice bag should not be too heavy. When this is not sufficient codeine in doses of half to one grain, and when necessary morphine, preferably in small doses (one eighth grain), should be used. Of great value is theobromine because of its action as a vasodilator of the coronary vessels, and as a diuretic. In the form of theobromine sodium salicylate (diuretin) it is best given in five or ten grain doses three times a day.

The patient should be made as comfortable as possible in every detail. He should have a free movement of the bowels daily.

In rheumatic pericarditis the patient must be watched continuously for any signs of acute cardiac failure. This is a rather frequent occurrence. When it occurs, the patient should be promptly digitalized.

ASPIRATION OF THE PERICARDIUM

The question frequently arises whether the pericardial fluid should be removed by aspiration. In the pericarditis of myocardial infarction or of uremia, this is practically never necessary. In rheumatic pericarditis, this is seldom necessary. Coombs says that he had never seen a case of rheumatic pericarditis where the removal of the fluid was necessary. This holds for the greater number of cases, but occasionally the evident presence of a large effusion with marked dyspnea and other symptoms calls for aspiration. I remember a case, that of a girl of eleven years, with a large pericardial effusion and marked dyspnea, in which after consultation, aspiration was postponed for a few days. The patient died suddenly the next afternoon.

Aspiration when properly performed is not a dangerous procedure. The chief danger is injury to the heart and the superficial cardiac vessels. The classical point of entrance, according to Sauerbruch (30) (p. 273), is the angle formed by the seventh costal cartilage with the base of the xiphoid cartilage. Another point for aspiration is in the fifth left interspace two to three cm. from the sternal border to avoid the mammary artery. Palfry (31) advises the fifth interspace internal to the left border of the pericardial dullness. The patient should be in half sitting or preferably in erect posture. The skin is anesthetized with novocaine (one half per cent.), and either an aspirating needle or fine trocar should be used. When the fluid is reached a change in resistance can be felt. The fluid then empties itself or a Potain aspirator is used. Improvement is immediate. Although ordinarily not a dangerous procedure, rare cases of sudden death have occurred, according to Sauerbruch, following puncture in the fourth or fifth space.

The treatment of purulent pericarditis is surgical. Klose and Strauss (32) have collected eighty cases of purulent pericarditis which were treated either with aspiration or with intercostal incision or by rib resection and free drainage. The results are as follows: of twenty-nine cases treated by aspiration four lived, or 10.4 per cent.; of twenty-seven cases treated with intercostal incision ten lived, or thirty-seven per cent.; of thirty-seven cases treated by rib resection and free drainage twenty-one lived, or 56.7 per cent.

Gynecological Operation in Insanity

ELLICE McDONALD, M.D.

Philadelphia

(*Concluded from page 27*)

This point of view in regard to psychoses is interesting in that it is more radical than the more conservative attitude of Broun and Taussig. It may, in part, be explained by the more recent onset of the psychosis in Bossi's cases as the results of operation will be better in the early stages of a psychosis. The claims of Bossi cannot be lightly dismissed as he is too good a gynecologist not to have his opinion carefully weighed.

Operation in the mentally disturbed may be divided into three classes: first, operation which is indicated for surgical lesions which threaten life; second, operation for lesions which produce upset metabolism for which the gynecologist would operate if the woman were sane, and third, operation for minor lesions, such as retroversion of the uterus, perineal lacerations, etc. In the first class of lesions threatening life, there can be no dispute as to the necessity of operation, and in the second class of lesions producing upset metabolism there can be but little argument that, if the danger of the operation is not great, these lesions (of which uterine myoma would be an example) had better be corrected.

The third class of lesions (of which retroversion of the uterus, painful menstruation and hernia are examples) occupy a more debatable ground. These are the cases upon which Bossi operates as a routine and reports mental recoveries after surgical measures. He is not alone in this belief as Schockaert (19) has reported a number of mental cures following correction of retroflexion of the uterus or other minor anomalies. He concludes that gynecological affections often insignificant in appearance, may, in some cases, be responsible for distressing psychopathies which may in turn be cured by a removal of the cause.

The proper course in these cases was very puzzling until the study of the vegetative nerve balance by Ludlum and myself (20) threw some light upon the mechanism. Pelvic troubles, such as pelvic infection or menstrual disturbances, will sometimes produce a local action upon the pelvic nerve, or pelvic branch of the vagus, so that this effect is visible in the smooth muscle reaction of the large intestine. The pelvic nerve (pelvic vagus, formerly called the N Erigens) supplies the pelvic viscera and the large intestine from Cannon's ring (about two fingers' breadth from the hepatic flexure) to the rectum. In certain cases it is possible to see vagus preponderance in the course of this nerve out of proportion to the rest of the vegetative nerve balance. In these cases it is usually possible to find some pelvic lesions, such as infection of retroversion, which will produce abnormal irritation of stimuli acting upon the central nervous system by intermediation of the vegetative nervous system to upset the functional balance. These cases have been approached very conservatively, but there is no doubt that selected cases can be much benefited and cured by properly chosen surgical measures. An example of such a case was one of toxemia of pregnancy where curettage cured the psychosis.

These cases, however, must be chosen each upon its own merits, and we have not been able to lay down any hard and fast rules for operation upon psychotic patients in these minor ailments. If all the cases of psychosis with retroversion were operated upon, more harm than good would result, but, in selected cases, benefit will accrue. In my own opinion, the amount of pelvic nerve disturbance weighs heavily for operation, because when this additional vegetative nerve upset is removed, the patient has an opportunity to recover, and in our experience it cannot be too emphatically stated that mental recovery is associated with recovery of the vagus sympathetic balance of the vegetative nervous system.

In the third class of minor gynecological ailments, operation is only done in selected cases after careful examination of the vagus sympathetic balance, consideration of the amount of pelvic nerve action and the relation of the lesion to vegetative nerve irritation. In certain lesions my opinion as to surgical operation is definite. Hernia is one of these lesions and my mature opinion (whatever it may be worth) is that all hernias should be cured by surgical measures in the mentally disturbed, unless there is some definite reason to the contrary, as age, coincident disease or prolonged psychosis. Hernia is in itself an expression of lack of vegetative nerve tone and plastic tonus as may be seen from the frequency of hernia in an old operation scar of the pregnant and is an expression of lack of calcium (which promotes protoplasmic rigidity of structure) and of vagus tone, so that hernia is more frequent in the sympathetic preponderants.

Operation in the psychotics is, then, done only after careful consideration and each case studied in all its own phases. Infection has not been found in anything like the percentage described by some observers.

Cotton (21) from the State Hospital at Trenton, New Jersey, states that it was necessary to remove the tonsils in ninety per cent. of all his patients who entered the State Hospital. He states that eighty-three per cent. of the male patients and seventy-six per cent. of the female patients were considered to have gastric infection and that twenty per cent. of the functional group had serious lesions of the colon. He found the cervix infected in eighty per cent. of the women. The seminal vesicles were found to be infected in fifty per cent. of the chronically insane men. Total colectomy was done in 133 cases with forty-four deaths (thirty per cent. mortality) and partial colectomy in 148 cases with fifty-nine deaths (forty-two per cent. mortality).

In the psychotic women examined by me at the Philadelphia General Hospital and elsewhere, no such percentage of infections as this has been found. At the time of the inception of this study, it was my belief, influenced by Cotton's reports, that a large

percentage of infection would be found. Such has not been the case. In my examinations of the patients in the psychopathic wards of the Philadelphia General Hospital and private hospitals, it has not been thought advisable to remove the colon in any case yet examined. Cotton's indications, as given in his paper, are 1, history of intestinal disturbance; 2, pain and tenderness in the right lower quadrant, and a certain amount of muscular rigidity, and 3, marked delay in the passage of the barium meal and over forty-eight hours.

These indications mean that the patient had an increased smooth muscle reaction, spastic colon and vagus preponderance. All the symptoms upon which Cotton bases his indications for colectomy may be readily explained by increased vagus action and preponderance. The history of intestinal disturbance is suggestive; the tenderness is almost constantly present upon both sides and in the hypogastric region. Tenderness upon pressure in the angle of the ribs and a little to the right is quite constantly present in vagus preponderance and, with a spastic colon, tenderness over the course of the colon, particularly at the head of the cecum, hepatic flexure and sigmoid is quite usual. Rigidity of the abdominal muscles is not common, although there is quite frequently resistance. The retention of the barium meal in the colon over forty-eight hours is a very common condition in sympathetic preponderance and even in spasticity. The meal often advances at a rapid speed to the colon which clamps down in spasticity and holds the barium meal for forty-eight hours or longer.

In other words, in my opinion, the cases as described by Cotton, for which he excises the colon, are cases of vegetative nerve upset. The radiographs which he gives in his article bear out this opinion and show typical vagus preponderance. No doubt there are cases in which there is infection as a source of disturbance of the vegetative nervous system and as a cause of mental psychosis, and, no doubt, there are also cases in which the colon is directly infected, but these cases are not common and not present in the proportion stated by Cotton. In my opinion it is extremely rarely necessary to remove part of the colon, and then only in cases with distinct and known pathological lesions such as tumors, obstructions, etc. Three reasons influence to this opinion, 1, the operation has a large mortality; 2, the indications must be definite and not vague, and 3, the operation does no good. In some cases, after colectomy, the lower part of the small intestine enlarges to take the place of the colon. In addition, the opinion of surgeons, who have had experience with colectomy after Lane's advocacy of the operation for intestinal stasis, is very decidedly against the operation as a therapeutic measure, except for known and definite pathological abnormality. In this opinion we concur.

Infected cervix uteri have been found by Ward Crampton (23), working with Cotton, in a very large percentage of cases (eighty per cent.). He believes that this infected cervix produces a similar intoxication to an infected tonsil and that removal will produce beneficial results to the psychosis. In this study at the Philadelphia General Hospital, infected cervices have been found in a very small percentage of cases, not one tenth of the percentage reported by Crampton and no gynecologist will believe that an infected cervix will produce symptoms commensurate with infected tonsils. So this operation, as a surgical procedure alone, has not been done.

Infection in psychoses and in bodily disease generally is often a terminal result rather than a cause, as cases of vagus preponderance seem to be prone to certain infections with the pyogenic organisms, just as the sympathetic preponderant are prone to pneumonia. Removal of an infection will often break the vicious circle and allow the vegetative nerve balance to recover. Infection will, of itself, sometimes produce a psychosis, but its place in causation is by no means that given by Cotton and his collaborators, and surgical procedures of the type he advises have not been practised by us.

An interesting fact in the study of surgical lesions in the insane is the little complaint they make of pain. Lesions which produce great pain are borne uncomplainingly and often discovered accidentally. Such a case was one of extreme hypertrophic cystitis, the most extreme ever seen by me. This woman died three days after her admittance to the Philadelphia General Hospital and the autopsy showed an ascending kidney infection and a marked hypertrophic cystitis with the bladder wall thickened to three c.m. No more painful gynecological lesion can be imagined and yet this woman made no complaint of pain. This faculty of bearing pain seems general among the insane women and is another reason for immediate gynecological examination of all women on admittance to the psychotic wards as attention is not directed to the gynecological lesion because no complaint is made.

Another interesting fact is the infrequency of cancer in the mental hospitals. In the British Isles (23), the incidence of cancer deaths in the insane hospitals is three per cent., while in the average population the cancer deaths are 12.4 per cent. No doubt cancer is quite uncommon in psychotic women for whatever reason.

Gynecological examination is not usually difficult in the mentally disturbed and, in my experience, an anesthetic is rarely, if ever, necessary. If difficulty is encountered, a morphine and atropine suppository usually produces enough narcosis, so that examination can be done in the stage of numb drowsiness. Before any patient is subjected to operation the consent of the relatives or friends is necessary: in the absence of friends, in the instance of state charges, the consent of the superintendent of the hospital must be obtained.

A Case of Rat Bite Fever in New Jersey

M. DE FRONZO, M.D.
Newark, N. J.

This case is being reported because rat bite fever is quite rare in the United States—particularly in the Eastern States. It is typical in every respect of rat bite fever as described by Osler, Castellano, *et al.* The specificity of the arsphenamines is also well demonstrated.

HISTORY

About August 1, 1923, the patient, a girl of two years, while asleep in a crib, was bitten on the left hand by a rat, which was scared away by the mother, who rushed to determine the cause of the patient's

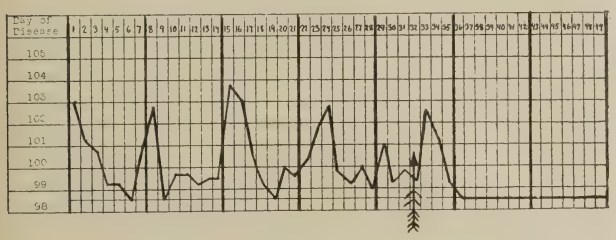

Fig. 1.—Temperature chart showing the rise in temperature to 103-104° about every seventh day.

crying. She found the baby's left hand bleeding quite profusely. Their physician was summoned and he cauterized the wound with phenol and applied a wet dressing. The child apparently showed no immediate ill effects.

Three weeks later, the mother noticed that the child became irritable, would not take its food well, and would not play with its parents as it formerly had done with enthusiasm. The child then became feverish, and its left hand became puffy. The family physician was summoned and he advised that the child be sent to the Newark City Hospital.

The child was then admitted to the surgical service of Dr. Randall with the following complaints: fever, puffiness of left hand, with swollen glands in axilla of same side, extreme irritability, scattered macular rash over body.

Physical examination revealed a well developed and nourished white girl of two years, with flushed cheeks, crying lustily and appearing acutely ill. Head, neck and chest were negative on examination. The abdomen revealed a spleen which was easily palpable at the costal margin. There was no pain or rigidity anywhere.

Glandular system showed cervical, axillary, and inguinal nodes all easily palpable. Those of the left axilla were enlarged to almost the size of a hen's egg. They were hot, red and tender to touch. No fluctuation.

The skin revealed a scattered maculopapular rash of reddish brown hue about two to five mm. in diameter, distributed over both shoulders posteriorly, chest, abdomen, both thighs, and dorsum of left foot.

On the dorsum of the left hand, there were three healed scars of a bite, with a bluish red discoloration about the size of a dime around the scars. The hand was swollen and puffy in appearance. There was no evidence of fluctuation anywhere. Red streaks ran up to the left axilla, where the nodes were visibly enlarged to the size of a hen's egg and quite tender to the touch. Epitrochlears were not felt.

A diagnosis of rat bite fever was made by me and the hand was put on saline wet dressings. All arsphenamines were withheld so that I could observe the clinical course of the disease.

Laboratory data revealed a blood count of total leucocytes 15,200; polymorphonuclears, 85 per cent.; lymphocytes, 13 per cent.; eosinophiles, two per cent.; hemoglobin (Dare), 85 per cent.; red blood cells, 4,-200,000. The urine was negative. Blood cultures were negative on two different occasions. About two c.c. of the patient's blood was injected into the peritoneal cavity of a white mouse. This mouse became quite ill. It bit another mouse a few days after inoculation and this second mouse also became ill. About a week later, both were autopsied but no spirochetes were discovered.

The temperature chart revealed the interesting fact that about every seventh day the child's temperature would rise to 103-104° F. Irritability would increase, the hand would become puffy and indurated; the lymphangitis and lymphadenitis markedly pronounced and the macular papular rash would stand out prominently. The temperature would fall by crisis and then all symptoms and signs would subside until the next paroxysm, when they would become pronounced again.

At the end of the fifth week, just before a fresh paroxysm was expected, I gave the child .2 gm. of neosalvarsan, dissolved in two c.c. of sterile normal saline, into the muscles of left buttock. The child's temperature rose from 98° to 102.6°—and then came down by crisis. Following this injection, the puffiness, lymphangitis, lymphadenitis and

maculopapular rash all disappeared. On the following day, the mother noticed and remarked that the the child appeared to be like her usual self, ate her food readily, played with anybody, did not cry and became more tranquil.

The child was kept in the hospital for sixteen days more after receiving the neosalvarsan with no recurrence of any of her symptoms. She was then discharged October 1, 1923, as cured.

She was seen again in the latter part of January, 1924, free from all signs and symptoms—the father remarking "the child never looked any better and was putting on weight rapidly."

196 Fairmount Ave.

Puerperal Infection: A Study of an Etiological Factor

DANIEL H. BESSESEN, M.D.
Minneapolis, Minn.

(*Concluded from page* 33)

Case VII.—A primipara, aged twenty-six, who has had measles, mumps, with no evidence of disease in the family, marital, social, occupational, or menstrual histories. On physical examination there was found varicosities of the left leg, and pregnancy. Prepared with ten per cent. mercurochrome and glycerine mercurochrome iodine solution, three hours and thirty minutes before final completion of labor. Delivered spontaneously, with first degree laceration of the perineum. Puerperium normal.

Case VIII.—Para five, aged thirty-two, had had measles, mumps, varicella, pertussis, variola, appendicitis, with rupture and abortion at five months, and two induced abortions at two months. On physical examination there was demonstrated a pregnant woman, with syphilis. Because of an occiput posterior position, a version was performed. Preparation with ten per cent. mercurochrome and glycerine mercurochrome iodine solution, seven hours before final termination of labor. Ten injections of arsphenamine and mercury salicylate given during the last trimester, apparently successfully relieved the luetic condition temporarily. The puerperium was entirely normal.

Case IX.—Primipara, aged twenty-one, with no history of illness of any sort in the family, marital, social, occupational, or menstrual histories. Physical examination was absolutely negative. Prepared with ten per cent. mercurochrome and glycerine mercurochrome iodine solution nine hours before final termination of labor. Delivered by medium forceps from an occiput posterior position with the cord three times around the neck of a dead female strangulated child. The delivery did not occur until the placenta was pulled away from the uterus by the extraction. Puerperium normal.

Case X.—A secundipara aged twenty-three who has had varicella and influenza, with no evidence of disease in the family, social, occupational or menstrual histories. On examination there was no evidence of disease. Prepared with ten per cent. mercurochrome and glycerine mercurochrome iodine solution five and a half hours before final termination of labor. Patient delivered spontaneously. Puerperium normal.

Case XII.—Patient was a para eight, aged twenty-six, living in poor surroundings, who has had a still born child at eight months and two miscarriages at two and four months, with no evidence of disease in the family, marital, social, occupational or menstrual histories. On physical examination there was found a small, anemic, undernourished woman of old appearance who was bleeding heavily from the vagina. Preparation with ten per cent. mercurochrome and glycerine mercurochrome iodine solution, which was also soaked on a tampon packed into the vagina. Delivered, placenta prævia, on an ambulance three hours later with a blood loss of one litre; 350 c. c. of citrated blood with 200 c. c. normal saline were transfused. Puerperium normal.

Case XII.—A para four who had had measles, mumps, typhoid, scarlatina, tonsillectomy, and a family history of tuberculosis in the mother, with an abortion at two months and no evidence of disease in the marital, social, occupational or menstrual histories. On physical examination there was observed a simple cyst of the thyroid, a lymphadenitis of the right axilla, mitral insufficiency and pregnancy. Prepared with ten per cent. mercurochrome and glycerine mercurochrome iodine solution one week preceding delivery. Only the perineal preparation was repeated at the time of delivery. Child delivered spontaneously with second degree posterior laceration of the perineum. Puerperium normal.

Case XIII.—Secundipara, aged twenty-six, who had had measles, whose husband is treating for syphilis without familial, occupational, social or menstrual evidence of disease. On physical examination there was found pyorrhea alveolaris with pregnancy. Patient was delivered spontaneously with Crede expression of the placenta, second degree laceration of the perineum. Prepared with ten per cent. mercurochrome and glycerine mercurochrome iodine solution eight hours before delivery. Puerperium normal.

Case XIV.—Para six, aged thirty-two, who had had scarlatina, measles, varicella, mumps, pertussis and pneumonia and varicose veins, with no evidence of disease in the family, marital, occupational, social or menstrual histories. On examination there was found an old laceration of the cervix uteri, old laceration of the perineum, erosion of the cervix, with cystocele and rectocele. Delivery precipitated from a left shoulder presentation with external manipulation. First degree laceration. Preparation with ten per cent. mercurochrome and glycerine mercurochrome iodine solution nine hours and thirty minutes before final termination of labor. Puerperium normal.

Case XV.—Para seven, aged thirty-one, who had had measles and varicella, no evidence of disease in the family, marital, social, occupational or menstrual histories. Physical examination showed a left pyelonephritis, cystitis with tendency to hypertension, incomplete prolapse of the uterus and pregnancy. Patient was in bed during the last trimester. Mother delivered spontaneously. Preparation was mercurochrome ten per cent. and glycerine mercurochrome iodine solution fifty minutes before termination of labor. Puerperium normal.

CONCLUSIONS

Puerperal infections have been recognized and treated since the earliest history of medicine. If the British definition of puerperal infection is accepted, it is found in from six per cent. to 22.9 per cent. of all deliveries with a mortality of 0.1 per cent. to .5 per cent. of morbid cases, and one out of four hundred of all deliveries. The etiological factors come from contaminated surroundings from contact, from operations and accidents of labor, from infections in other parts of the body, but the majority of cases arises from the bacteria present in the vagina. The mechanism of entrance of these bacteria into the uterus is the mechanism of labor, especially the second stage. Factors which facilitate this entrance are operative delivery, long labor, Crede expression of the placenta.

To prevent this, the vagina must be sterilized. The technic of vaginal sterilization is presented—paint the introitus, vulva, perineum with ten per cent. mercurochrome, inserting a speculum lubricated with glycerine mercurochrome iodine solution. This technic applied to sixteen cases shows excellent results.

SUMMARY

Historical factors and the data of present day occurrences of puerperal infections are presented here with the summary of the etiological factors—emphasis being placed upon the vaginal flora as the origin of a large percentage of infections during the puerperium: the methods of attempting sterilization of the vagina are reviewed and a technic for vaginal sterilization presented.

Brain Diseases*

JOHN WILLIAM SHUMAN, M.D., F.A.C.P.
Los Angeles

Here brain diseases is used in the broad sense,—diseases of the central nervous system. Internists should be able to recognize and differentiate the functional from the organic. To this end, your previous training in anatomy and physical diagnosis was given. Experience, however, will be your best teacher. Only the high spots can be touched upon at this clinic. Space forbids other than brevity.

After treating a patient for headache for a long time with much dope and little thought; or a case of vomiting as "stomach trouble"; or vertigo, disturbed vision, group muscular weakness, and a number of other things; and afterwards learn that a brain tumor was the cause of these symptoms which were treated as a disease,—you will then be learning medicine.

Remember the tripod headache, vomiting, and choked disc, support a diagnosis of brain tumor.

A chief fault we doctors have is faulty memory,—the inability to remember essential things about our case and cases. Few of us can, when it is necessary, reel off the twelve cranial nerves thinkingly and recognize disturbances in them and interpret the same. If one can do this much has been mastered towards the making of a neurologist. We must be able to test superficial and deep reflexes from pupils to plantar and know how to interpret them.

The fact that we are oftimes defeated in the proper recognition of a brain tumor, also in its character and location, is no reason why we should not tackle it.

Meningitis forms a large percentage of brain diseases and may be meningococcic, streptococcic, pneumococcic, or staphylococcic, syphilitic, tuberculous, or what not in origin. It may complicate empyema of mastoid, ethmoid, sphenoid cells or maxillary and frontal sinuses, or come from a boil on the upper lip, or from many other causes.

Meningismus or cerebral irritation is not to be confused with meningitis. Not long ago a doctor when asked, "How could you make a diagnosis of epidemic cerebrospinal meningitis?" answered, "By spinal puncture!" Much was wrong with his training. He, you see, skipped history and physical findings entirely,—highly essential things before diagnostic trauma of the spinal canal should be considered.

The sudden onset of agonizing headache, projectile vomiting, fever, tachycardia, cervical rigidity, a positive Kernig and Brudzinski with a leukocytosis and an increase of polys makes the diagnosis of acute suppurative meningitis more than a mere guess. Spinal puncture may then be demanded on three counts:

First—For drainage (therapeutic),
Second—For examination, and
Third—For introduction of antimeningococci, serum if due to meningococci which are extracellular and intracellular, and gram positive.

Tuberculous meningitis is more slow in onset. Characteristic as to temperature curve, has a lymphocytosis, and a focus of infection elsewhere, such as in the lungs, peritoneum, or other locations. Remember the conelike percipitate which settles out in the spinal fluid and in which the acid fast organisms can be found.

*First of six clinics held for the Seniors of Coll. of Med. Evang., Los Angeles at the L. A. G. H., March 18, 1926

Remember also that typhoid fever, tuberculosis, measles, malaria and influenza are diseases in which a leucocytosis does not occur. Lymphocytosis does occur in measles and tuberculosis. A leucopenia usually occurs with typhoid and influenza.

Never forget that syphilis is an exceedingly common cause for brain disease and can be of the coverings or deeper structures and simulate poliomyelitis and epidemic encephalitis or polioencephalitis. History and physical findings are important. Look for a scar of a previous sore on the penis, vagina or lip, an adenitis, disturbed reflexes, gait and station and as a check up, but less important, a four plus Wassermann.

In history taking leading questions are not good. For example,—"When did you have a sore on the penis?" is much better than, "Did you ever have syphilis?" The latter will invariably draw a "no." Do not be easily led or one will be too often misled—by a scar on the penis. When finally arrived at a diagnosis, try to disprove it. If it withstands such an attack it is more likely to be correct.

Do not be afraid of consultations with other internists, neurologists, ophthalmologists, röntgenologists and surgeons in reference to brain diseases. They have taught me much. The laity will like it and it will often help your patient,—The one you are after all most interested in.

Leave hysteria out of your diagnostic vocabulary, also neurasthenia. These are symptoms and not yet understood properly enough to be interpreted like fever, vomiting, rheumatism, anemia and a lot of other disease symptoms which were once treated by our forefathers in medicine as diseases per se,—and I regret to state by some physicians today.

Read up on whatever case you have under question. One case well studied is worth ten just snapped at.

If you put all brain diseases on the organic basis and work them out accordingly you'll not be as far wrong as to assume they are, "Functional until proven otherwise." It is now known that encephalitis not only causes "shaking palsy" (loss of coordinate function), but other things which heretofore we diagnosed functional diseases.

In reference to functional diseases, let us remember a few things, "diagnostic pegs" I call them. First that the hall mark of paranoia is suspicion. That in dementia precox "the individual is stranded on the rock of puberty." That illusions, delusions and hallucinations figure strongly in these two diseases, also in confusional insanity, that a slurring speech speaks for disseminated sclerosis. The acute manias or madness of high fever, alcohol and other intoxication and coma from many causes, e. g., so-called sandbag, diabetes and uremia, are not difficult as a rule to differentiate unless the sandbagged individual was morphinized and alcoholized at the same time and was a diabetic.

The sense of smell will recognize the alcohol on the breath or the fruity odor of the diabetic (acetone). With morphine the pupils are contracted unless blindness, a glass eye, adhesions about the iris, a cataract or something else interferes. A urinalysis will find sugar if present, also albumen and casts.

Apoplexy of the cerebral type usually accompanies arteriosclerosis. Hypertension and enlarged left heart usually occur in a person over forty years of age.

It is almost axiomatic that the man who makes a diagnosis in cases where other men fail, does not do so because of superior intelligence. All may be equally well trained but the one man observes every detail of his examination systematically and thoroughly and has a definite method of approach to his problems, whether it be neurological, obstetrical or surgical.

The man who is alert and will quickly note a unilateral exophthalmos, a positive Rhomberg, a difference in knee jerks, will often make the diagnosis the other man has missed.

An illustrative case[1] then shown by Dr. Legget. A "brain tumor suspect." The diagnosis based upon history of two year periodic attacks of headache, vomiting, and epileptiform seizures. The latter often followed by hours or days of unconsciousness. Weakness and twitchings in the left side of face, hand and leg. After more observation and study a decompression operation by his surgeon will be done.

[1]M. Cousins, through the kindness of Dr. Carl Rand, Brain Surgical Service, Los Angeles General Hospital.

Treatment of Gonorrheal Arthritis by Vasotomy with Special Reference to the Study of Vesiculograms

GEZA GREENBERG, M.D.
New York

Following the teaching and pioneer work of Belfield in the treatment of gonorrheal arthritis, I have in the last five years undertaken the study of this disease by injecting the vesicles either through the open operation as advocated by Belfield, or through the ejaculatory ducts by way of the urethra by means of a special cystoscope devised by me.

In the course of my investigations I have studied the seminal vesicles röntgenologically immediately after the operation to determine the size, configuration, amount of distension and relative position of them; and, in addition to that, I have taken serial radiographs on consecutive days to ascertain the length of time necessary for the vesicles to thoroughly empty themselves.

The position of the vesicles in the average case is midway between the horizontal and vertical planes of the body. This, however, is not constant, it varies not only in different individuals, but very often the two vesicles in the same individual vary as to size

and position. The more nearly they approach the vertical plane, the better the drainage and, hence, the shorter the period of convalescence, and, conversely.

Furthermore, the condition of the prostate through whose substance the ejaculatory ducts pass to their destination on the surface of the veru montana determines the character of drainage from them. Thus a chronically enlarged and inflamed prostate prolongs indefinitely an infection of the vesicles, and establishes a vicious circle.

Contractions of the bladder, levator ani muscles and possibly the perineal muscles at the end of micturition aid vesicular drainage to a great extent. The more horizontally the vesicles are placed, the easier it is to reach them, for then they are usually distended, whereas, in a vertical position, they, usually being empty on account of better drainage, are farther removed from the examining finger.

That absorption takes place largely through the seminal vesicles has been amply demonstrated by Eugene Fuller, who obtained excellent results in gonorrheal arthritis by draining them. This operation has not been popular with the profession on account of apparently technical difficulties.

That absorption proceeds from the vesicles can be accounted for by the anatomical considerations. The vesicles are fibromuscular tubes about six inches long when unraveled. In the true anatomical state as we find them, being coiled on themselves, and about two inches in length, they present a rather large absorbing surface; and, in view of the lymphatic supply, which forms three distinct networks, one in the mucosa, one in the muscularis and one in the outer coat, one can readily see the ease with which infection can spread to the general circulation. The prostate, too, contributes its share to systemic infection.

In order to treat gonorrheal arthritis successfully, it is requisite that it can be recognized and combated early before secondary changes take place in the joints. It is by no means a monoarticular disease as has been taught; on the contrary this is rather the exception. Usually a number of large and small joints are involved. There is a tendency for an infection of the tendon sheaths, as well as for exostoses of bones, notably that of the os calcis to develop.

When the arthritis is acute it must be differentiated from acute rheumatic fever. One important differential point is that, in rheumatic fever which is distinctly migratory in type, the disease travels so rapidly as to involve almost all the joints in a comparatively short time; but in so doing, the joints which were at first attached may be entirely free from any signs of inflammation, whereas in gonorrheal arthritis the infection rarely extends quite so rapidly, but if it does it is unusual for it to subside entirely in the joints first involved. The fever is higher in rheumatism and associated with a good deal of sweating and prostration, whereas in gonorrheal arthritis the fever and pain are less marked, and sweating is not conspicuous unless associated with purulent joints, or secondary to antipyretics used. The antecedent history of previous relapsing attacks of tonsillitis, arthritis, cardiac or nervous manifestations, in the absence of sexual exposure, past or present gonococcal infection, favors the diagnosis of rheumatic fever. On the other hand, a history of sexual exposure, of acute or subacute urethritis in the presence of gonococci in the urethral or adnexal smear, or a history of repeated attacks of urethritis, even in the absence of the specific organisms, should awaken a suspicion of a possible gonorrheal arthritis. Occasionally the two diseases may be associated together, and then it requires a good deal of diagnostic acumen and circumspection to determine which of the two is predominating.

Syphilis in its chronic stage quite often attacking joints, must be differentiated from gonorrheal and rheumatic arthritis by its insidious onset, by its less acute state, and hence causing less pain and tenderness; furthermore, the history, the Wassermann and therapeutic tests should clear up the diagnosis.

Tuberculous synovitis must always be considered when only one or two joints are involved. However, the age, history, general condition and x ray findings should settle the diagnosis.

Arthritis deformans must also be differentiated from gonorrheal arthritis by its very insidious onset —often taking years for its full development—its symptoms at first being vague, represented by stiffness, creaking and pain, while the bony changes set in later.

On the other hand one must not lose sight of the possibility of septic absorption from the genital and urinary tracts even in the absence of an active gonococcal infection giving rise to joint involvement, the infection being caused by other pyogenic organisms, not unlike the absorption proceeding from the nasal sinuses, tonsils and teeth.

The urethra must be carefully examined for strictures, which often are a source of infection. The prostate and the seminal vesicles must be the object of a thorough and painstaking examination. The prostate may feel normal to the touch, and yet be the seat of a follicular infection, which can be determined only by a microscopic examination of the expressed secretion, and by a cystourethroscopic examination, when pus may be seen gushing forth from the prostatic follicles.

In the course of a cystoscopic examination one may glean considerable information about the state of the seminal vesicles, particularly when they are indurated and surrounded by a perivesicular infiltration, causing a marked protuberance in the region of the ureters with the formation of decidedly prominent ridges issuing from them to the internal sphincter. At times the infiltrate around the base of the bladder may be so extensive and dense as to raise the entire trigone, and convey the impression of a beginning midlobe hypertrophy of the prostate, or a hypertrophied trigone. The proximity of the vesicles to the trigone with their accompanying pathological condition is sufficient to account for the frequency of urination associated with seminal vesiculitis. The possibility, in intractable cases of vesiculitis, for the infiltrate to extend underneath the subtrigonal tissues as far as the internal sphincter, and possibly the prostatic urethra, with secondary contraction of the sphincter, is by no means precluded. Then, again, the induration may be sufficiently extensive to travel upward in the direction of the ureters, encroaching upon their lumen and causing the formation of hydroureter and hydronephrosis. The latter has been proved clinically.

During a cystourethroscopic examination one may for radiographic purposes inject the ejaculatory ducts,

preferably with a solution of thorium, sodium iodide, or sodium bromide instead of the opaque silver collodial preparations, which blur the field of vision. When the vesicles have been sufficiently distended with any of these media, they become more readily accessible to the examining finger in the rectum. On numerous occasions since 1917 the ejaculatory ducts have been catheterized and medicated by me through a special direct vision cystourethroscope, which I have designed for that purpose.

In order that the seminal vesicles stand out prominently in vesiculograms, it is necessary that they be thoroughly stripped of their secretions and the bowels freed of their contents prior to the injection.

The following points must be studied from the vesiculogram: 1, their shape or configuration; 2, their size and degree of distension; 3, their relative position to each other and to the different planes of the body; 4, the number of convolutions and possible distortions which may subsequently interfere with perfect drainage from them, and lastly as to the length of the time necessary for the vesicles to thoroughly drain their contents without any outside interference. The latter can be determined by taking radiograms on consecutive days until the opaque medium can no longer be perceived. Since drainage is such an important factor in seminal vesiculitis, and as its character can be so easily studied from the vesiculograms, one can appreciate the extreme necessity of this additional information both for prognosis and treatment. In the course of my investigations I have learned that, if the vesicles are favorably situated for drainage, and that is if they approach nearer the vertical than the horizontal plane of the body, there is no residuum found in them from twenty-four to forty-eight hours after injection. Such cases clear up in a comparatively short time, and yield readily to the simple vasotomy operation and retrograde injection of the vesicles, or to intraurethral injections by way of the ejaculatory ducts. If, on the other hand, the vesicles retain the opaque solution at the end of forty-eight hours, the probability is that they will continue it for a long time, and unless relieved surgically, will indefinitely feed the system with toxins. In some cases the drainage is so poor that days or possibly weeks after the injection the radiogram shows a very marked distension of the vesicles. The contour of the vesicles will vary according to the etiological factor. If the upper part of the vesicles reveals a dilated sac and the lower extremity signs of imperfect drainage, it, in all likelihood, is indicative of swelling of the upper convolutions of the vesicles; whereas, if all portions of the vesicles are dilated, the point of obstruction must be looked for either in the excretory duct of the vesicles, or in the ejaculatory ducts. They, the ejaculatory ducts, in turn, may be the primary seat of inflammation, by extension from the urethra, or compressed from without by the inflammatory exudate of the prostate.

From all this it is evident that the treatment will depend on the underlying pathological condition. The majority of cases respond readily to the Belfield operation. In order to facilitate the accessibility of the vas for subsequent injections, I have, in some minor details, modified the classical Belfield operation.

The upper part of the scrotum just below its junction with the root of the penis is selected as the site of operation. The scrotum and penis are thoroughly painted with a solution of three per cent. picric acid in alcohol; then the scrotum in its upper angle with the contents of the cord is grasped by the left hand, and injected with one per cent. novocaine solution through the skin, exposing the cord and all its layers of fascia; each layer is dissected separately and held between clamps until the vas and the rest of the contents are brought into view. The vas with its bloodvessels is sharply dissected away from the cord and by means of tape held up, while the other structures are dropped back into the wound. The fascia are now brought together by several sutures to form a floor for the vas. The vas is then stripped of some of its fascial covering for a distance of about one and a half inches, avoiding the artery of the vas, and incised in its longitudinal axis with the point of a tenotomy knife. The incision should be barely long enough for admitting a needle of 20 or 22 bore. I have used a special platinum needle of 20 provided with two rings, made for me by the Kny-Scheerer Corporation. The needle, while resting in the vas, is fastened to the skin by means of a suture passing through the rings. In order to secure additional immobility of the needle within the vas while manipulated in the course of the injections, I have used a rubber tubing four inches long and attached to an adapter of a Luer syringe connected with the hub of the needle. This attachment prevents jarring and possible dislodgement of the needle. The solution is then injected into the vas. In the majority of cases I have used from fifteen to twenty c. c. of twenty per cent. argyrol solution and followed it up with sufficient sterile water to wash out thoroughly the lumen of the vas. On the other hand I have in quite a number of cases used with equal satisfaction a one per cent. solution of silver nitrate. Great care must be exercised in preventing leakage into the tissues. If any solution has accidentally escaped into them it should be immediately washed out with salt solution. For additional security a small rubber drain is inserted which is removed at the end of twenty-four hours. The wound is now ready to be closed by one suture. The injection is carried on daily for three days through the needles which are left in the vas. At the end of three days they are removed.

While the vasotomy operation does not necessarily terminate the gonorrheal infection in all cases—although it is indispensable in many complicated cases of gonorrhea in conjunction with the routine treatment—it does, nevertheless, clear up in a remarkably short space of time the most painful arthritic lesions in the great majority of patients.

OTHER TYPES

The cases that do not respond to the vasotomy operation, as indicated by the clinical course of the disease, or by the vesiculograms showing imperfect drainage, must eventually, after repeated failures from other methods of treatment, submit to more radical surgical measures such as vesiculotomy or vesiculectomy combined with prostatomy.

To sum up, the majority of gonococcal arthritis cases respond to the simple vasotomy operation and injection of the vesicles with silver solutions; if they do not, they must be submitted to major surgical measures provided they utterly fail to respond to the

usual methods of treatment. Injection of the vesicles unquestionably shortens the period of convalescence.

CONCLUSIONS

In conclusion, I should lay down the choice of treatment of gonorrheal arthritis in the following sequential order:

1. A vigorous routine antigonorrheal treatment including all known accepted measures.

2. Injection of the ejaculatory ducts through the urethra.

3. Vasotomy under local anesthesia; failing in this then.

4. Exposure of the prostate and vesicles by means of an open perineal dissection under perfect visual direction, draining or removing the vesicles as one sees fit, and draining the prostate at the same time.

Abscess of the Parotid Gland Following Acute Membranous Tonsillitis

A. LOBELL, M.D.

New York

CASE

Mrs. A. R., aged forty-four, married. The important points in her past history are, that she was subject to tonsillitis and that she was suffering from a progressive type of catarrhal otitis media.

On March 27, 1923, general and local symptoms of an acute tonsillitis developed. The tonsils presented a nondiphtheritic membrane. A streptococcus was found to be the cause of the condition. She improved under the ordinary therapeutic measures.

On April 3rd, she complained of pain in the left ear. An examination showed nothing abnormal in the ear. One could elicit some tenderness in front of the tragus and at the angle of the jaw.

April 5th, the left parotid gland was swollen, resembling mumps. She had dryness of the mouth and painful deglutition. The constitutional reaction was severe. The temperature was 105° F. She was delirious at times and the prostration was marked.

April 8th, the entire gland became brawny and the skin pitted. Gentle pressure over the gland with simultaneous milking of the duct from the buccal surface yielded pus at the papilla. The diagnosis was thereupon quite evident. After consultation with the family physician, it was decided to postpone surgical interference temporarily.

Within forty-eight hours, the constitutional symptoms began to subside and the diffuse suppuration appeared to localize into distinct areas of pus collections. One appeared behind the ear and one in front of it. The latter was the smaller of the two because there was spontaneous drainage through the duct.

On April 14th, the posterior abscess was opened and considerable pus was evacuated. Rubber tissue drains were inserted and the wound healed promptly. Cultures from the pus showed a streptococcus identical to the one found in the tonsillar infection.

As soon as the posterior wound began to close the anterior abscess increased in size. It was decided to operate on this abscess also. Drainage through the duct alone was apparently insufficient. A horizontal incision on a line parallel with Stenson's duct was made in order to avoid injury to the duct as well as to the branches of the facial nerve. The healing of the wound was prolonged because a large quantity of salivary secretion was discharging frequently through the wound. For a time it appeared that a fistula would result, but fortunately after several cauterizations the wound healed. The patient was discharged about the middle of June, 1923.

The patient was seen about six months later. While there were no ugly scars, there was, however, a noticeable depression on that side. This was naturally due to the loss of some of the parenchymatous tissue of the gland.

CONCLUSIONS

1. A streptococcic tonsillitis was the immediate cause of a suppurative parotitis. The bacteria obtained from the tonsils and from the gland were identical.

2. This complication resulted in a prolonged illness and a permanent deformity.

3. Drainage through the duct is unreliable. Multiple abscesses are likely to be formed on account of the lobular arrangement of the gland. While there may be some communication between the individual abscesses, perfect drainage is not to be expected through such channels. Each collection of pus will require a separate incision.

4. The question arises, did the infection travel through the duct or lymph and blood channels? One may be inclined to think that an ascending infection through the duct is the most logical way. There are, however, points against this assumption. If infection through the duct were favorable, this complication would take place more often because tonsillar infections occur so frequently. Besides, there are other sources of infection in this vicinity, namely, pus coming from the nasal sinuses through the nasopharyngeal route, pyorrheal and dental infections. Foci of infection within the thoracic and abdominal cavities are more frequently causes of suppurative parotitis and the blood carries the infective material to the gland in these instances.

5. The infrequent occurrence of suppurative parotitis as a result of throat infections is well illustrated in a report of fifty-four cases by Blair and Padgett (1) of Chicago in the *Archives of Surgery*, July, 1923. In this large series, only four cases were due to various throat conditions.

1420 Grand Concourse.

The Preclinical Period and Prophylaxis of Diabetic Gangrene*

HENRY S. STARK, M.D.
New York

While the literature of diabetes has grown to enormous proportions, it remains a conspicuous fact that little of it has been devoted to that phase of diabetes which forms the subject of this communication. It would be difficult indeed to account for this lack of concentration of the medical mind on a topic which from its frequency and seriousness should have invited intensive study. The importance of prophylactic measures to prevent or, at times, to arrest the onset of gangrene has practically been overlooked in our more ambitious efforts to cure the diabetes *in toto*. However, when we recall that every diabetic over fifty years of age is potentially liable to gangrene, and that one in fifty of all diabetics die of gangrene, we can readily understand why this terminal incidence should, in reality, receive as much consideration as the general therapy of the diabetes itself, for a great deal can be accomplished in the way of prophylaxis by judiciously combating certain symptoms which are the inevitable heralders of gangrene—symptoms which are so constant as to give rise to what I may style "a gangrene complex" or syndrome, which once established makes for a serious prognosis.

AVERTING GANGRENE

Some years ago, becoming impressed with the frequency of gangrene as a terminal incidence (namely, about fifteen per cent. of cases), and with the oft time futility of treatment in frank cases, it occurred to me that preventive medicine might offer something in the way of averting gangrene, whether of the diabetic or of the senile type, providing that efforts were directed to the prevention of the endarteritis or the arteriosclerosis frequently set up by the toxic or foreign elements in the circulation—namely, glucose, acetone bodies, or the end products of protein metabolism. If it were possible to secure a normal volume of normal blood to the lower extremity and thereby retard structural and degenerative changes in the vascular coats, it seems reasonable to believe that gangrene could be staved off in a generality of cases. Theoretically, this seems plausible, and I have good reason to believe that on more than one occasion I have succeeded in averting gangrene and thus extended the patient's tenure of life.

Broadly translated, this means that all diabetics during the gangrenous period of the disease—say about fifty years of age—whether or not they display evidences of malnutrition of the limbs, must be looked upon as gangrene suspects. This dictum presses with double weight upon those obese diabetics with an hypertension and those with a complicating nephritis or a myocarditis. Such diabetics need careful watching. Though there be no subjective evidences of approaching gangrene, careful physical tests may reveal that they are in the preclinical stage. At this time, a diabetic presents the following picture: He is over fifty years of age, is likely to be obese with increased blood pressure, has a weak pulmonic second sound, his urine may show renal elements. Over one third of all diabetics of ten years' standing are nephritic. That has been my experience, though some observers claim that this figure is too high. He suffers occasional pains—cramplike—in one calf, even when at rest; or else he may have severe burning pains radiating along the course of a large nerve or bloodvessel of the lower limb. In another group there may be present burning pains of the foot lasting for from a few minutes to several hours, accompanied by redness of the skin, possibly some swelling at the sole, with a point or two of tenderness to pressure. In still another group there may be pains in the calf after a short walk, relieved only by coming to a standstill. When, in addition to these symptoms, there is diminished pulse beat at the popliteal, the anterior or posterior tibial, or dorsalis pedis artery, while the foot itself is cold and clammy to the touch, perhaps dusky in appearance—in all such instances gangrene is imminent. The blood supply is already markedly impaired, while the vascular coats are already the site of lesions.

EARLY SYMPTOMS

Concisely expressed, the earliest premonitions of gangrene are the following: Firstly, pain in the leg accompanied by paresthesias or trophic disturbances; secondly, changes in the lumen of the arteries; and thirdly, diminished pulsations of the dorsalis pedis artery. One cannot emphasize too strongly the importance to the patient of recognizing a case of threatened gangrene rather than to diagnosticate a case of frank gangrene; in the former instance one can hold out hope of a comparatively long life; whereas in the second instance one cannot offer more than a life constantly hanging in the balance.

Since the advent of insulin therapy, the life expectancy of these patients has taken on a more favorable turn. My own files contain a number of cases of threatened gangrene, others even of actual gangrene, in which a course of insulin administration and of appropriate dieting was followed by the disappearance of all signs of circulatory and nutritional disturbances. In other words, there was ample reason to believe that the insulin resulted in partially regenerating the diseased Islands of Langerhans and thus restoring the physiological function of the pancreas. This incidence has been observed frequently, both in human and in canine diabetes. In my own experience I can point to a number of such cases, while followup memoranda of my patients have disclosed no recurrence of the diabetes. In like manner, we can attribute a cure of the endarteritis of diabetic origin to insulin therapy. Several of my cases come under this category, as was visually demonstrated by x ray plates of the bloodvessels of the lower extremity, before and after treatment. These plates showed a disappearance of the arterial sclerosis, thus indirectly emphasizing the value of röntgen photography in all suspected cases of atheroma of bloodvessels; for in diabetics, as proven by necropsy, there occurs a high incidence of arteriosclerosis, which may be readily recognized.

*Read at the February, 1926, meeting of the Clinical Society of the Hospital for Joint Diseases.

That these results were due in part to the use of insulin, there can be little doubt, especially when the improvement in the vascular coats was followed by an amelioration of all the classical symptoms of diabetes. The prophylactic lesson that this experience teaches is that advanced diabetics should be studied röntgenologically at stated intervals for the detection of vascular lesions. A negative plate is an asset in the prophylaxis of gangrene; a positive plate clouds the prognosis. I have recently had a run of cases of complicated diabetes in which a sclerosis of bloodvessels of internal organs was clearly demonstrable, röntgenologically; for example, a patient with outstanding gastric symptoms showed an arteriosclerosis, mostly central in type, involving the celiac axis. Another case of persistent vomiting revealed a sclerosis of the splenic artery. Vascular disease of the lower extremity, if prophylaxis is to be of any avail, must always be anticipated. Once sclerosis or extensive thromboses are proven ocularly, the patient becomes a gangrene suspect. In addition to vascular changes, x ray photos may show changes in bone, such as a beginning bone necrosis or an osteomyelitis.

PROPHYLAXIS

Knowledge of the causation of disease furnishes the clue for prophylaxis; therefore therapeutic measures directed to the prevention of gangrene will embrace: Firstly, the treatment of diabetes itself; and secondly, the treatment of complicating affections, more particularly circulatory and cardiac complications. Before the days of insulin, it was my practice to lay greater stress upon the treatment of the complications than upon the original disease itself—being under the impression that under all circumstances diabetes was a progressive disease that terminated fatally and was rarely amenable to treatment. Today, thanks to experimental therapy, the table is turned in favor of the diabetic, and it is now not unusual to check the progress of the disease. One patient whom I treated in the fall of 1922, and three whom I treated in the summer of 1923, are still sugar free, but under dietary surveillance. Whether they can be designated as cured cases is problematical; at any rate, their power of assimilation for carbohydrates is greatly improved.

INSULIN

The most efficient agency for the prevention of gangrene is insulin, judiciously employed, at the right moment. Whenever circulatory disturbances are manifest in the lower extremity, do not withhold it. Often it will tide the patient over a critical period, and determine the question of gangrene or no gangrene. The aim of treatment is to improve the circulation by means of a normal column of blood—one as free of glucose, acetones, or other foreign substances as it is possible to secure, hoping thereby to enable the diseased coats of the bloodvessels to repair themselves. Whenever one or all of the three signs before mentioned appear, insulin with dietary control is in order. The patient must be on his back, with the foot of the bed raised. Unless the patient consents to keep in the prone position for a long time, treatment will be ineffectual. Naturally, such a procedure entails much hardship and many sacrifices, but desperate conditions call for desperate measures. Rest is the one essential, without which the probability of preventing gangrene is *nil*. I have kept patients on their back for a month or more, but I have saved them from gangrene, and these patients have their legs today. Whenever cardiac symptoms are present—such as pseudoanginal attacks, weak pulsations. weakness of the heart sounds, evidences of decompensation, arrhythmias, or local signs of circulatory disturbance, the need for physical rest is more emphatic. Such a diabetic is a candidate for gangrene. His need of rest is more pressing than his need of digitalis.

IODIDES

Such patients are put on a course of Burnham's soluble iodines, keeping it up for weeks—beginning with eight drops an hour before meals, and increasing by two drops every second day until the patient is taking about thirty drops in plenty of water three times daily. This preparation is easily assimilated, readily absorbed, and rapidly eliminated. It reduces vascular spasm and lowers hypertension; it seems to me to stay the progress of atheroma of the bloodvessels. Diabetics seem to have a remarkable tolerance of it. Two of my patients have now been taking it continuously over a period of two months without signs of gastric irritation or of iodism. It seems to exercise a favorable influence on arterial disease, at least for a time; however, there is no assurance that an aggravation of the sclerosis may not recur, for once a diabetic becomes a gangrene suspect he remains a gangrene suspect the remainder of his life, his lease on life depending upon the period of time he can remain sugar free. This means that the other diabetic, the one in the pregangrenous period, must be treated as energetically as the diabetic in middle life. We must get away from the popular fallacy that old age is an asset to the diabetic. In the public mind, old age is an insurance against the ravages of diabetes. This is plainly fallacious as far as the advent of gangrene is concerned, and of its complications.

A therapeutic measure which is often followed by gratifying results is the application of light and heat rays. This procedure should be employed in all cases of threatened gangrene from vascular disease, more particularly those cases which are accompanied by vascular spasm and pain and sluggish circulation. The relief from pain seems to be due to a reduction of the congestion that is usually a factor in endarteritis. Radiant energy also serves to supply artificial heat to an extremity that is always cold from faulty circulation. Treatments are given three times daily, fifteen minutes at a time, care being taken not to provoke a severe erythema. These seances are followed by gentle massage. Ultraviolet reactions from deep therapy lamps are not, in my opinion, followed by beneficial results.

PASSIVE EXERCISES

A method of treatment devised by Dr. Leo Buerger, of New York, known as Buerger's passive exercises, has received favorable recognition. I employ this method in every case of threatened gangrene; its purpose is to induce an artificial and temporary hyperemia in a limb which is always cold and pale due to a poor blood supply. This treatment, when applied daily and with due care for details, as outlined by the author, will often—not invariably—improve the circulation of the lower extremity.

There are certain details of prophylaxis which should be emphasized in the care of diabetics during the pregangrenous period, which, if ignored, may lead

to disastrous consequences. All diabetics should avoid infection of the foot by guarding against traumatism, either selfinflicted or at the hands of the chiropodist; in the same manner, pressure points from tight footwear should be avoided. At all times the feet must be kept warm and clean, the legs should never be crossed and whenever possible they should be elevated.

IMPORTANCE OF STUDY

When we stop to consider that there are in the United States, according to Joslin, over one million diabetics; and further recall that there are another million persons who are candidates for this disease by reason of heredity or familial tendencies; and, still further, that of this vast number probably one seventh or one eighth will acquire gangrene, the question of prophylaxis looms up as a mighty one. I know of no more laudable ambition on the part of the profession than to give this problem the same study and enthusiasm that it has so successfully given to other therapeutic problems.

1309 MADISON AVENUE.

Dislocation of the Carpal Semilunar Bone.

A Report of Eight Cases

EARL D. McBRIDE, M.D.
Oklahoma City, Oklahoma

The purpose of this article is: 1. To emphasize the disastrous results which can come from failure in early diagnosis and treatment. 2. To portray some distinguishing features chief of which is a fixed deformity of the hand characteristic of neglected cases. 3. To draw some conclusions from cases presented and quoted in the literature as to what to expect regarding permanent disability and method of treatment.

INTRODUCTION

The relative frequency of the injury is briefly discussed with reference to the importance of never failing to keep it in mind when Colles fracture is suspected but not found.

LITERATURE

It is pointed out that various authors who have written on the subject differ widely as to severity of disability and advice as to treatment. This status of the subject is dangerous and confusing so that attempt is made to briefly sum up experiences of various authors and come to some conclusions as to diagnosis, prognosis and treatment.

PATHOLOGY

In neglected cases, the wrist and hand assume a deformity which is constant and as characteristic of this condition as silver fork deformity is to Colles fracture. The cause of this deformity is discussed and attempts made to clear up disputed questions of pathology.

REPORT OF CASES

Eight of my personal cases are quoted in detail. They present well the variations in complications, the results of treatment at different stages, and the possibilities as to final amount of permanent disability under various circumstances.

Case I.—Simple uncomplicated dislocation forward of carpal semilunar. Diagnosis overlooked by competent x ray specialist and attending surgeon. Treated for sprain eight weeks. Severe pain required saturation with morphine. Dislocated bone removed on ninth week. Marked relief in pain. Characteristic fixation deformity of wrist and fingers permanent. Patient died three years later in hospital for the insane, a morphine addict.

Case II.—Multiple injuries of extremely severe type. Dislocation of the semilunar and fracture of scaphoid not diagnosed until fourth week. Characteristic deformity had developed. Semilunar and scaphoid fragment removed at fourth week. Permanent disability to a marked degree.

Case III.—Unreduced dislocation of semilunar of five months standing. Has characteristic deformity but of mild degree. The semilunar was removed. Permanent disability not sufficient to prevent manual labor.

Case IV.—Laborer in broom factory. Nature of accident such that exact mechanics of cause of dislocation were observed by the patient. Semilunar replaced at end of second week by open operation. Result one hundred per cent. perfect.

Case V.—Removal of dislocated semilunar and proximal fragment of scaphoid two months after accident. Fifty per cent. useful hand.

Case VI.—Reduction of semilunar three months after injury. Original method of fixing bone in normal position is described. Result, slightly painful on certain movements because of traumatic arthritis but returned to manual labor.

Case VII.—Dislocation of semilunar and fracture of scaphoid examined three years after injury. No attempt at reduction had ever been made. Suffered intense pain for many months. Was treated for sprain. Result, surprisingly good function in wrist and hand. The patient is at present working as an electrician.

Case VIII.—Dislocated semilunar removed by another surgeon three days after injury. Result, practically normal function of wrist and hand. Not a laborer. Wrist becomes painful while playing tennis.

TREATMENT

Conclusions are drawn from the foregoing material as to the best method of handling the injury and its complications.

Practical Therapeutics

The Hepatic Depressor Principle and Its Oral Administration in Hypertension

HENRY R. HARROWER, M.D.
Glendale, Calif.

The profession is well aware of the interesting and, perhaps, epochmaking developments with a product separated from the liver by certain fractional solvent methods, which is being used both experimentally and clinically in the reduction of high blood pressure.

A number of articles have appeared calling attention to various aspects of this work (1, 2).

Since at least a part of our work with this principle has paralleled that of these other investigators, and their early reports already have been published, it is useless to recapitulate our own experiences with what is probably a similar product.

I wish, however, to announce a development which should be quite important. We have succeeded in separating from the hepatic residue, a product which is active when administered by mouth. I believe that this is an original development, for, so far as I can find, no other work has been done along this line.

Since this substance works so remarkably when administered by injection, it is quite natural to conclude that it is unnecessary to administer it by mouth. I realize that there is a tendency in some parts to decry the oral administration of organotherapeutic products and to lean toward the use of active principles which are separated as completely as possible from their original endocrine source, and administered either by the intramuscular or the intravenous route, as is the case in the laboratory experiments which usually are preliminary to clinical tests.

The records will show that I have an abiding faith in the efficacy of active endocrine products administered by the mouth, and in view of the fact that the encouraging experiences during the last two or three years with insulin have developed a coincident neurological condition amounting almost to a phobia and sometimes known as needle horror, many a physician would welcome an insulin that is active by mouth. These unfortunate experiences have given a more tangible turn to one of the first comments made regarding the advent of insulin by Dr. A. D. Blackader (3): "A treatment which would necessitate frequent subcutaneous injections is always handicapped at the outset."

At all events, in December of last year, after quite an extended experience with this active hepatic principle, a small number of tablets were made up by vacuum concentration of the solution. In the intervening time we have given this product, ourselves, to thirty-seven patients, and, through interested colleagues, to over one hundred additional persons. Besides this, a series of tests with presumably normal medical students has been made in fifty-six cases, and it is upon these 193 cases that I purpose to base my following comments and conclusions.

First of all, it is my opinion that the hepatic residue, which we have been using, contains a true active endocrine principle from the liver, in view of the fact that it has been purified as far as possible, from every associated depressor substance including histamin. (A few words regarding this must be added: Practically every animal extract contains a certain amount of protein derivatives one of which is known as histamin. Macdonald remarks that his product is freed as far as possible from this material, and that his experience with liver substance demonstrates that its influence upon blood pressure, as compared with that of histamin, is less rapid in its onset and more prolonged in its influence.)

This endocrine principle is believed to act chiefly upon the liver, and its presence has been suspected for many years and has been referred to by a number of writers including myself in the book (4), in the following words: ". . . The study of the functions of the liver has been carried on for many years, and as yet we are still very much in the dark as to how this remarkable organ performs its equally remarkable work. The supposition that the liver itself is a source of hormones has been mentioned by several writers, and the fact that its detoxicating function is conceded to be greater than that of any other organ seems to give weight to this suggestion."

"Lorand believes—and his opinions are corroborated by A. Gilbert, H. Strauss, and others—that the liver is a gland with an internal secretion that is strongly antagonistic to intestinal poisons, destroying toxic products brought to it from the intestine by the portal vein. This antitoxic power claimed for the liver is dependent, not upon the blood that may be present in the organ, but upon the liver itself, and the activity of this organ in destroying toxins must be due to some chemical substance at present unknown. A part, at least, of this power remains in vacuum dried extracts, and is probably the source of the benefits which follow its therapeutic administration."

This new principle then, is believed to be this "substance at present unknown," the influence of which is presumed to affect, in a hormonic, catalytic fashion, that part of the hepatic service to the body which concerns detoxication.

The detoxicative activity of the liver may be properly called "anabolism" for it is the business of the liver to build up certain urea precursors like ammonium carbamid, guanidin, cyanamin, and other products into urea. It is this ureagenetic function of the liver that was presumed to be regulated by endocrine influences, originally I think, by MM. Gilbert and Carnot, in Paris, as far back as 1896, at the same time, by the way, that Dr. Oliver and Dr. Schafer, of Edinburgh, were calling the attention of the profession to the pressor influence of the adrenal medullary principle.

I am of the opinion that this hepatic depressor sub-

stance accomplishes its clinical effects upon blood pressure through a true endocrine influence upon the liver detoxication, and parallel with our efforts to perfect it for oral administration, we have been trying to prove to our satisfaction, that it does not act in a pharmacodynamic depressor manner like histamin or the nitrites.

Here are some of the clinical experiences which lend weight to our position: Aside from its capacity to reduce blood pressure in certain cases, it has certain distinct clinical limitations. Administer this anabolic principle to a case of renal impermeability or nephrosclerosis and it has practically no effect whatever. Administer it again to another case with marked arteriosclerosis, and while it may have a slight effect, the results are practically negligible. The nitrites, however, will reduce blood pressure quite markedly, though temporarily, in virtually every case, and it is believed that they do so by certain vasomotor changes, or circulatory gymnastics as they have been called.

Again, a number of patients receiving this hepatic principle have remarked upon subjective personal betterment aside from any change that may have been brought about in the blood pressure. A number of them have felt that there must be something else in the tablets beside a remedy to influence blood pressure. As one of them remarked, "It doesn't make any difference what my blood pressure is today, I know I am a lot better, because I feel better," and this patient didn't believe in Christian Science either.

Now the failures in organic or structural cases with the original hepatic solution were really the first indications to me that the product was not a depressor drug, and, as we have gone along, we have used several laboratory procedures to supplement our sphygmomanometric work. Certain cases with very high pressure, have been obviously toxic and suffering from hepatic derangement. The urine was highly acid, there was a generous trace of indican and the total solids were low. More recently, we have been studying these people from the standpoint of the urinary ammonia and in many cases this is found to be unusually high. This particular syndrome of urinary findings is exactly that which I discussed in several papers published during 1908-10, and we now know, according to Dr. W. M. Barton, of Washington, D. C., that the presence of indican in the urine is "an indication of the detoxicative capacity of the urine." In other words, indican in the urine is not so important an indication of intestinal putrefaction and toxemia, as it is of the inadequacy of the detoxicative disposal of this substance by the liver. It is also believed that the increase in the amount of urinary ammonia, by Malfatti's test, is an indication of a similar hepatic defect, for here the ammonia precursors of urea have not been properly fitted together and they are eliminated in a half way stage.

It may be mentioned that the products of protein metabolism, already referred to, as they reach the liver are highly toxic in small quantities, that they are known to have a decided pressor effect and that urea, despite its bulk, is practically nontoxic, and has no noteworthy effect upon the tension.

Every effort has been made to avoid drawing conclusions that were unwarranted. For instance, it has been suggested that this was merely a toxic substance, which, as with injections of many other proteins, would cause a minor degree of anaphylactic shock with consequent reduction in the blood pressure. There is no shock nor local reaction, nor feeling of illbeing following its use. Besides, injections of foreign proteins into the body cause rapid and transitory changes in the blood pressure, while the effect of this principle, both by mouth and injection, is not so sudden and in many instances, lasts for several days. The type of the reaction to it, therefore, leads us to disbelieve that its influence is due to a form of poisoning.

Again it has been suggested that this residue contains a substance directly antagonistic to adrenin, which interferes with its presumed continuous pressor effect, thus reducing the blood pressure. While I believe in the reality of the clinical state known as hyperadrenia, and that undue stimulation of the adrenals can cause high blood pressure, I do not concede that the results we have been seeing are due to the neutralization of adrenin. It is true that in our animal work we have found, when determining matters pertaining to toxicity and dosage, that rabbits and dogs receiving lethal doses of this hepatic principle, are benefited and their lives saved by suitable doses of epinephrin. This is also true of the use of this drug in various other serious toxic states including the vasomotor paralysis of shock, the serious hypoglycemia of insulin overdose, and in reactions following mass doses of certain other drugs such as arsenic and others.

Just because the abnormal use of this hepatic principle, e. g., in massive dosage in animals, can cause shock and death and because this can be neutralized largely by injections of epinephrin, does not mean that adrenalin normally balances the anabolic, endocrine principle of the liver in the ordinary way, but rather, that epinephrin overcomes the detrimental, physiological reaction caused by its ill advised administration. Incidentally, it is an accepted opinion that the pancreas and the adrenals are directly antagonistic to each other, and that insulin and adrenin are physiological opposites. I cannot believe that this applies also to the liver principle.

Some of the physicians with whom we have been in contact during this investigation, have questioned the accuracy of my assumption that this is an endocrine principle from the liver and that it increases its detoxicative function, or as I have put it "stimulates anabolism."

We have frequently noted that patients receiving this product, and especially the tablets, express themselves favorably upon their own subjective feelings of well being. Granted for the moment that the increase of blood pressure in many functional cases is due to adrenal irritation with a coincidental excess of the adrenal principle, as indeed it might well be, it seems that any plan calculated to encourage the principal detoxicating mechanism of the body—that of the liver—should hasten the destruction of the irritating protein split products which overdrive the kinetic system, and in particular the adrenals. If treatment with this anabolic principle really lessens this toxemia, mitigation of some of the results of the toxemia (through the adrenals upon the pressure) should follow. Perhaps this is exactly how this anabolic,

catalytic influence upon hepatic detoxication actually brings about its depressor effects.

There is another aspect to this upon which we have sought to assure ourselves. If the salutary depressor influences which follow the use of this product in cases with high blood pressure are not due to an endocrine influence or any other kind of an influence upon hepatic detoxication, but, as has been suggested, are a result of a sort of neutralizing effect upon the normal or abnormal amounts of adrenin present in the organism, or are pharmacodynamic in character we should be able to reduce the normal blood pressure by administering this product. Further, if it works in this fashion, its influence should be noticeable under practically all circumstances—in normal as well as hypertensive states. Apparently it does not work this way, for in a series of tests covering a period of ten days in fifty-six medical students, the general impression gained was that this substance has practically no influence upon the normal blood pressure.

The average figures gained from this series of trials may be stated here: Before the test the tension was 116 systolic and 73 diastolic; after it was 114 and 68. The change following the preliminary purge two days before the tablets were started was greater than this negligible variation.

In view of the above, I conclude that, if the liver function is not especially abnormal and, correspondingly, the toxemia is not great, the conditions in which anabolic, hepatic stimulation is called for, are not present, and therefore, we do not get a particularly marked reaction from its use.

On the other hand, report after report indicates that this substance is indeed active when given by mouth. It will not be possible to report the entire series of cases of which we have figures, and I will admit that we do not have any reports extending over a period of many months. The longest time during which a patient under observation has taken this oral product is fifty-eight days, and in this particular instance the blood pressure brought down as far as possible by hygienic measures and previous treatment, was 200-100, and at the end of approximately two months, it was 188-110—a negligible reduction in the systolic tension and even an increase in the diastolic—but as our coincidental studies proved, this patient has renal sclerosis, regarding which I shall have something to say shortly.

A most interesting case has just finished the second week of study. At the beginning of the first week this patient's blood pressure was 188-100 and there was considerable discomfort, dizziness and apprehension. No changes were made in her mode of living, eating or in her work. At the end of seven days, having taken only seven tablets—one each day—the blood pressure was 155-94.

Another case confirmed my faith in the oral activity of this product. A middleaged woman, with what was said to be arteriosclerosis, had for eight weeks been under intensive treatment with diet, elimination and the nitrites. Her systolic pressure was originally 260, but at the time the use of these tablets was started, the pressure was 200-110 and had been stationary for some weeks. The dose in this case was arranged so that the patient consumed fifty tablets, four daily. each representing one c. c. of a hepatic solution which, when administered to a dog weighing ten kilograms, would reduce the blood pressume 12 mm. Her blood pressure at the end of this period was 160-90, and the patient was obviously better subjectively.

Still another patient receiving only tablets started in with the preliminary figure of 220-140. A routine procedure[1] was carried out and the first seven days of the report read as follows:

Date	*Dose Tabs.*	*Syst.*	*Diast.*	*Change*
4-23	1	220	140	——
4-24	2	210	140	10/0
4-25	3	195	136	25/4
4-26	3	185	128	35/12
4-27	3	185	120	35/20
4-28	3	170	115	50/25
4-29	3	166	108	54/32

Still another case in which the figures were uniform was treated in this same routine manner and at the same time with the following results:

Date	*Dose Tabs.*	*Syst.*	*Diast.*	*Change*
4-24	1	215	100	——
4-25	2	212	100	3/0
4-26	3	204	98	11/2
4-27	3	198	95	16/5
4-28	3	195	95	20/5
4-29	3	192	95	23/5
4-30	3	187	93	28/8

Some average figures may be interesting. A series of forty ambulatory cases were treated with varying amounts of this substance and over varying periods. Not all responded well; some were sclerotic cases in whom the changes were negligible. The average reduction amounted to 29 mm. in the systolic, and 12 mm. in the diastolic.

If it is desired merely to prove the activity of the product when given by mouth in suitable cases, a still more remarkable series of average figures can be shown. However, these figures are not true averages. for all the sclerotic cases were excluded, and the maximum drop in tension is recorded—it does not always remain at the lowest point. This series of figures is made up from fourteen cases and is as follows: Average before treatment, 196-111; maximum low figure 154-93, an average reduction of 42-18.

In the course of our studies we have encountered a number of failures and as has already been mentioned, these failures are largely due to sclerotic processes which accompany the hypertension. I do not want to say that this method is contraindicated in this type of case because it seems to have caused some slight changes in several and to have some beneficial effect, but we have come to the conclusion that, when a case makes absolutely no response during a period of not more than a week, the renal function test with phenolsulphonephthalein is going to be below normal. In fact we are almost expecting that a diag-

[1]The following outline was mimeographed and sent with testing supplies of these tablets: "After a preliminary day of fasting, a purge and other hygienic care so as to reduce the blood pressure as much as possible (many patients who have been under treatment for some time already have their hypertension reduced as much as possible and therefore may proceed without these preliminaries), give the patient one tablet in the morning; on the second day two tablets, one in the morning and one in the evening; on the third day, one morning, noon and night; and on the fourth day either the same amount or an additional, fourth, dose. This makes ten tablets in all —the contents of one trial package as at present put up.

"The blood-pressure, systolic and diastolic, should be taken at least once a day, preferably twice. It should be taken before the tablet is swallowed and, as far as possible, at times which in relation to work, activity, meals, etc., are identical each day, for comparative purposes. Do not take the blood-pressure of a patient who has just hurried up the stairs or finished a meal."

nostic measure may be developed upon these experiences.

It is not easy in practice to secure a series of twenty-four hour urine specimens and to make charts of the variations in elimination of certain products. However, we have accumulated enough figures to warrant the presumption that in individuals with toxemia, obvious hepatic insufficiency (endocrine), and hypertension, we may frequently find an increase in the urinary ammonia, and that with the control of the toxemia and the reduction of the blood pressure, there is a coincidental reduction in the ammonia figures.

CONCLUSIONS

I believe that I am justified in drawing the following conclusions from this work:

1. The liver is a gland of internal secretion whose endocrine function is concerned with detoxication, i. e., the destruction of certain metabolites of protien origin.

2. These waste substances are toxic in extremely small quantities; and normally, should be built up by the liver by the process known as ureagenesis, into a nontoxic and easily eliminated waste product, namely, urea.

3. That, where high blood pressure accompanies defective hepatic detoxication, the work of the liver can be increased, and the pressure reduced by the administration of a residue separated from the liver by fractional solvent methods.

4. This anabolic, endocrine principle is not destroyed by digestion, but is quite promptly active when given by mouth. The dosage of this substance should depend upon the status of the patient and should vary in proportion to the response to it.

5. Since the effect of this principle is believed to be catalytic and its influence is brought about through the liver, its effects upon hypertension are predicated upon the presence of an underlying defect in the hepatic detoxication. Its therapeutic value, therefore, should be in proportion to the extent of the toxemia, the hepatic character of the difficulty, and the capacity of the liver to respond to such stimuli. This opinion is further substantiated by the fact that certain persons respond very noticeably to even small doses of this substance, whereas other causes, equally functional in type and just as free from sclerotic changes, respond less rapidly and for a shorter time. Further, in presumably normal cases the effects are negligible.

6. This influence upon the liver is not permanent, but the present status of our early patients indicates that the effects are quite similar to those expected from organotherapy, that is, a gradual educative influence which tends to reestablish a more nearly normal function on the part of the organ that is being treated.

7. The principal interference to the success of this new measure in the treatment of high blood pressure is sclerosis, and sclerosis of the kidneys has a more marked detrimental effect than arteriosclerosis.

8. Finally, the effect of this substance when given by mouth has not at any time been accompanied by any cumulative or detrimental influences; but, on the other hand, irrespective of the degree of depressor effect brought about, in many instances a subjective benefit has been noticed.

Antitetanic Serum in Tetanus.—A. C. Harrison (*International Journal of Medicine and Surgery,* Vol. XXXVIII, No. 12) finds that prophylaxis is far more important than therapeutics in the treatment of this disease. In considering the prophylactic treatment special stress should be laid on the proper care of wounds at the earliest practicable moment. Wounds properly handled from the beginning are subject to tetanus so rarely as to make it almost negligible. On the other hand some types are so subject to the disease as to make the administration of prophylactic serum mandatory.

In a general way it may be said that wounds occurring in those who work about stables, wounds produced by explosives, crushed wounds that are ground full of street dirt, and all other wounds in which the surgeon is uncertain as to the thoroughness of sterilization, should have prompt prophylactic treatment.

No very clear case can be made out for the value of antitetanic serum as a therapeutic measure, nor can we as yet say what is the best mode of administration. A careful study of the available literature fails to prove the sure value of any particular route or dosage. Up to the present the evidence seems to me to indicate that the result depends much more upon the virulence of the infection and the susceptibility of the subject than upon any special treatment. But it is equally certain that we have no better treatment than serum and therefore it should be used.

As to the routes, the evidence seems to indicate that it is best to combine several routes. Eg. intrathecal, intramuscular and subcutaneous or intravenous, intramuscular, intrathecal. All are debatable and only time and careful study can determine what is best.

Thermocautery in Minor Surgery, Especially in the Treatment of Mastitis.—F. Starlinger (*Wiener klinische Wochenschrift,* May 21, 1925) reports very favorably on the use of the thermocautery in certain conditions. The largest part of the author's cases consisted of circumscribed, localized infections, ranging from slight early infections to large carbuncles of the neck in diabetics. The lymphangitis disappeared on the following day and the infiltration and pain disappeared. On the third day the patient was usually able to be up and about, carrying only a small dry dressing. The cautery point should be sharp. Similar results were observed in the case of furuncles. On withdrawing the cautery, the pus exudes, a wet dressing is applied and the part is put at rest. Good results and rapid are also obtained in carbuncles. The cosmetic results in hemangioma are excellent. The Pacquelin may also be used in severe hemorrhage following the extraction of teeth and in neoplasms that are easily injured, as those on the gums, in the ear, nose, etc. Folliculitis and the common wart are also indications.

The thermocautery is an ideal instrument for the treatment of mastitic abscesses, but it is contraindicated in the diffuse, interstitial inflammations of the mammary gland.

The great advantages of this mode of treatment are: a saving of time, instrumentarium, bandage material, personnel, and painlessness of subsequent treatment, and the abolition of drainage.

Treatment of Nasal Diphtheria Carriers.—Clara Israeli (*Journal of Laboratory and Clinical Medicine,* April, 1925) used a ten per cent. ichthyol ointment for the treatment of diphtheria carriers on five consecutive days. The method was carried out as follows: A piece of absorbent cotton was wound tightly on the end of an applicator, and as much of the ointment as would hold on the end of the swab was carried gently all the way into the nasal cavity, entering the nasopharynx; another swab is used in the same way in the other nasal orifice. This procedure is recommended as simple, inexpensive, and easily applied. The time is comparatively short, depending on faithfulness of the application.

Incidence of Pulmonary Complication Following Ether and Ethylene-ether Anesthesia for Surgical Procedures in the Upper Abdomen*

JOHN S. LUNDY, M.D.

Rochester, Minnesota

In order to establish a statistical basis for the comparison of ethylene-ether and ether in their efficacy, and their effect on postoperative pulmonary complications and mortality, the results in two parellel series of six hundred cases have been tabulated. To make the two series analogous, each operation under ethylene-ether has a corresponding operation under ether, the site of the operation being similar, and the date and meteorologic conditions identical in each pair. Operation in the first case in each series took place January 1, 1924, and in the last case December 31, 1924. So far as conditions could be controlled the only variant was the anesthetic.

Ether was administered by the usual open drop method. When ethylene and ether were combined, a machine was used for controlling the amount of each. The greatest possible percentage of ethylene was used and only enough ether added to bring about surgical anesthesia. On account of the nature of the operation, greater relaxation is required for operations on the gallbladder than for those on the stomach, and sometimes several ounces of ether were necessary in the former. In such cases, although the anesthetic was classed as ethylene-ether, it was practically little different from ether.

The data bear chiefly on postoperative pulmonary complications and their relation to the original lesion, to the type of anesthetic, and to preliminary medication. The postoperative period is the time spent in the hospital after operation. Data with regard to age, sex, and operative risk are also presented. Consideration of the cause of postoperative pulmonary complications and the reported statistics of others may be found in the current literature. (1-19.)

striking difference occurs in the number of cases of postoperative bronchopneumonia, 1.7 per cent. following ethylene-ether and 4.6 per cent. following open drop ether. There was even a greater difference in the number of post operative cases of bronchitis: 0.3 per cent. after ethylene-ether and 3.2 per cent. after ether. The incidence of pohstoperative cough following ethylene-ether was five per cent. and following open drop ether one per cent., but a number of patients in the ethylene-ether group were operated on before a preoperative cough subsided, while in the ether group most of the patients had no cough at the time of operation. The anesthesia was considered satisfactory in eighty-five per cent. of the ethylene-ether cases and in 84.2 per cent. of the ether cases. Anesthesia was considered satisfactory when the patient's color was good; there was no rigidity, no mucous or struggling, and generally no difficulty with the anesthetic at the time of operation. The surgical mortality in each group is 2.1 per cent. Six of the patients with duodenal ulcer who were given given ether, six died; in three cases I considered the anesthetic partly responsible for their deaths. They represent 0.7 per cent. of the 280 cases of duodenal ulcer in which ethylene-ether was given and 33.3 per cent. of the deaths in this particular group.

Of the 280 patients with duodenal ulcer who were given ether, six died;; in three cases I considered the anesthetic partly responsible. In each group there was practically the same number of patients who used tobacco excessively. There were, no doubt, many other patients in each group who used tobacco but were not so recorded. Statistics relative to the effect of tobacco are not included in the tables.

Gastric ulcer (*sixty-six cases*).—Half the patients in this group were given ethylene-ether and the other half open drop ether. The percentage in each group is about the same as regards sex, risk, and preliminary medication. Nine per cent. of the patients given ether had brochopneumonia, while none of the patients given ethylene-ether had it. The incidence of bronchitis was the same in each group, as was that of postoperative cough. Satisfactory anesthesia was obtained in 93.9 per cent. of the patients given ethylene-ether and in 81.8 per cent. of the patients given open drop ether. There was only one death in the gastric ulcer group, and in that case ether had been given. I did not consider the anesthetic at all responsible for the death. There were no deaths among the patients given ethylene-ether. There were about the same number of persons in each group who used tobacco to excess.

Cholecystic disease (*574 cases*).—Half of the patients in this group were given ethylene-ether and the other half open drop ether. The percentage in each group is about the same as regards sex and risk but there is quite a difference in the preliminary medication. None was used in 52.9 per cent. of the ethylene-ether cases and in 76.6 per cent. of the ether cases. Morphine or morphine and atropine was given in 47.1 per cent. of the ethylene-ether cases and in only 23.4 per cent. of the ether cases. Bronchopneumonia developed in 1.4 per cent. of the cases following ethylene-ether and in 2 per cent. of the cases following ether. After each type of anesthetic pulmonary embolism occurred in 0.3 per cent. of the cases. Bronchitis appeared in 0.6 per cent. of the ethylene-ether cases and in 1.7 per cent. of the ether cases. There were twice as many cases of pleurisy (two per cent.) following ether as there were after ethylene-ether. Postoperative cough was present in 5.9 per cent. of the ethylene-ether cases and in two per cent. of the ether cases. Satisfactory anesthesia was obtaind in 78.3 per cent. of the ethylene-ether

cases and in 88.1 per cent. of the ether cases. The mortality in the ethylene-ether group was one per cent., and in the ether group, 1.7 per cent. In one case of cholecystic disease (0.3 per cent. of the gallbladder cases) in which ethylene-ether was used, I considered the anesthetic partly responsible. This one death is 33.3 per cent. of the deaths occurring in the cases of cholecystic disease following ethylene-ether. I considered the anesthetic partly responsible for three deaths (one per cent.) following operation for cholecystic disease when ether was given. These three deaths are sixty per cent. of the deaths following the administration of ether in cases of cholecystic disease.

Cholecystitis with cholelithiasis (344 cases).—The entire series of cases of cholecystitis has been divided according to the presence or absence of cholelithiasis. Gallstones were present in 344 cases. In half of them the anesthetic used was ethylene and ether, and in the other half open drop ether. The percentage as regards sex and risks was about the same in the ethylene-ether group and the ether group. Of the 172 cases of cholecystitis with stones in which ethylene and ether was administered, no preliminary medication was used in ninety-one (52.9 per cent.), and morphine or morphine and atropine was used in eighty-one (forty-seven per cent.). In a similar group in which ether was used, preliminary medication was omitted in 136 cases (seventy-nine per cent.), while morphine or morphine and atropine was given in thirty-four (19.7 per cent.). Of these cases in the ethylene-group postoperative bronchopneumonia appeared in two (1.1 per cent.); and of a similar number in the ether group, postoperative bronchopneumonia appeared in four (2.3 per cent.). There was one case of pulmonary embolism in each of these groups. Postoperative cough occurred in 7.5 per cent. of the cases after ethylene-ether and in 2.9 per cent. of the cases after ether. Satisfactory anesthesia was obtained in 77.9 per cent. of the cases in the ethylene-ether group and in eighty-six per cent. of the ether group. Death occurred in one case (0.5 per cent.) of those in the ethylene-ether group; I considered the anesthetic partly responsi-

ble. Death occurred in five cases (2.9 per cent.) in the ether group; I considered the anesthetic partly responsible in three instances.

Cholecystitis without cholelithiasis (230 cases).—Each type of anesthetic was administered to half the patients. The percentage was much the same as regards sex and risk. No preliminary medication was used in fifty-three per cent. of the ethylene-ether cases or in seventy-three per cent. of the ether cases. Morphine, or morphine and atropine, was used in 46.9 per cent. of the ethylene-ether cases and in twenty-six per cent. of the ether cases. The incidence of postoperative bronchopneumonia was the same in the ethylene-ether group and the ether group (1.7 per cent.). Postoperative cough occurred in 3.4 per cent. of the cases in the ethylene-ether group and in 1.7 per cent. of the cases in the ether group. Satisfactory anesthesia was obtained in 79.1 per cent. of the ethylene-ether cases and in 91.3 per cent. of the ether cases. There was a mortality of 1.7 per cent. in the ethylene-ether group. I considered neither one of these two deaths due to the anesthetic. There were no deaths among the patients who were given ether.

COMPARATIVE RESULTS WITH REFERENCE TO THE ANESTHETIC (Table 1)

Comparison of the six hundred cases in the ethylene and ether group with the six hundred cases in the open drop ether group shows the totals to be much the same in each as regards sex and risks. On the whole, there was considerable difference in each group in the number of patients given preoperative medication; morphine, or morphine and atropine, was administered in 45.6 per cent. of the cases in the ethylene-ether group and in 31.8 per cent. of the cases in the ether group. Bronchopneumonia occurred in 1.5 per cent. of the cases in the ethylene-ether group and in 3.6 per cent. of the cases in the ether group, regardless of the type of upper abdominal operation performed. Pulmonary embolism occurred in three tenths per cent. of the cases in the ethylene-ether group and in one tenth per cent. of the cases in the ether group. Bronchitis following ether (2.5 per cent.) was much more common than after ethylene and ether (six tenths per cent.). Postoperative cough was found in 5.5 per cent. of the ethylene-ether cases and in but 1.8 per cent. of the ether cases, an explanation for which has already been offered. Anesthesia was rated as satisfactory in 82.3 per cent. of the ethylene-ether cases and in 86 per cent. of the ether cases. There was a mortality in the ethylene-ether group of 1.5 per cent. (nine cases) and in the ether group of 2 per cent. (twelve cases). Of the nine cases of death in the ethylene-ether group, I considered the anesthetic partly responsible in all but three instances. Of the twelve cases of death in the ether group, I considered the anesthetic partly responsible for the outcome in six instances.

RESULTS IN THE ENTIRE SERIES

In 60.8 per cent. of the cases there was no preliminary medication, and in 38.7 per cent. there was preoperative medication. Postoperative broncho-

In 47.5 per cent of all deaths the anesthetic was at least partly responsible (ethylene-ether was responsible for 18.9 per cent and ether was responsible for 28.5 per cent of the deaths). In 41.6 per cent of deaths following duodenal ulcer the anesthetic was at least partly responsible (ethylene-ether was responsible for 16.6 per cent and ether was responsible for 25 per cent of the deaths). In 62.5 per cent of deaths following cholecystic disease the anesthetic was at least partly responsible (ethylene-ether was responsible for 25 per cent and ether was responsible for 37.5 per cent of the deaths). Twenty-nine per cent of all patients that had bronchopneumonia died.

pneumonia occurred in 2.5 per cent. of the twelve hundred cases. Bronchitis occurred in 1.6 per cent. of the cases and postoperative cough in 3.6 per cent. The anesthetic was satisfactory in 84.1 per cent. of the cases. There was a surgical mortality of 1.7 per cent. There were nine deaths (seven tenths per cent. of the series) for which I considered the anesthetic partly responsible. I considered the anesthetic at least partly responsible for 42.8 per cent. of all the deaths.

COMPARATIVE RESULTS WITH REFERENCE TO PRELIMINARY MEDICATION (Table 2)

Operations for duodenal ulcer under ethylene-ether (280 cases).—In 55.8 per cent. of these cases no preliminary medication was employed. There was no postoperative bronchopneumonia among these cases, while it occurred in 4.7 per cent. of those cases in which morphine or morphine and atropine was employed. Satisfactory anesthesia was obtained in 80.1 per cent. of the cases in which preliminary medication was omitted, in eighty-six per cent. of those in which morphine only was given, and in 93.8 per cent. of those in which morphine and atropine was given. Death occurred in 1.2 per cent. of the cases in which no preliminary medication was used; I considered the anesthetic partly responsible in one instance. Death occurred in one (2.3 per cent.) of the cases in which morphine alone was given; I considered the anesthetic partly responsible in this case. Death occurred in 3.7 per cent. of the cases in which morphine and atropine was given; I did not consider the anesthetic responsible.

Operations for duodenal ulcer under ether (280 cases).—In 58.1 per cent. of these cases no preliminary medication was used. Bronchopneumonia appeared in three per cent. of these cases, in 9.8 per cent. of the cases in which morphine only was given, and in 4.7 per cent. of the cases in which morphine and atropine was given. In two cases atropine only was given and in neither was there any postoperative pulmonary complication. Satisfactory anesthesia was obtained in 83.5 per cent. of the cases in which there was no preliminary medication, in 80.3 per cent. of those in which morphine only was given, and in 88.8 per cent. of those in which morphine and atropine was given. Death occurred in three (1.8 per cent. of the cases in which no preliminary medication was used, and I considered the anesthetic partly responsible for death in one of them (33.3 per cent.). There were no deaths in the cases in which morphine only was given. Death occurred in three cases (4.7 per cent.) in which morphine and atropine had been given; I considered the anesthetic partly responsible for death in two of these.

Operations on gastric ulcer under ethylene-ether (33 cases).—No preliminary medication was used in eighteen (54.8 per cent.) of these cases; bronchopneumonia appeared in none of them, and anesthesia was satisfactory in 94.4 per cent. Satisfactory anesthesia was obtained in one hundred per cent. of the cases in which morphine was given, and in 91.7 per cent. of those in which morphine and atropine was given. There were no deaths following operation for gastric ulcer under ethylene-ether.

Operations on gastric ulcer under ether (33 cases).—No preliminary medication was used in twenty cases (60.6 per cent.) of this group; bronchopneumonia occurred in three cases (fifteen per cent.); bronchitis developed in five per cent., and postoperative cough was present in five per cent. Satisfactory anesthesia was obtained in eighty-five per cent. of the cases in which no preliminary medication was instituted. Death occurred in five per cent. of the cases and I did not consider the anesthetic even partly responsible. No postoperative pulmonary complications occurred in the cases in which morphine only had been given. In the cases in which morphine alone was given satisfactory anesthesia was obtained in 66.6 per cent. In the cases in which morphine and atropine was given no postoperative pulmonary complication occurred; satisfactory anesthesia was obtained in 85.7 per cent. and there were no deaths.

Operations on the gallbladder under ethylene-ether (287 cases).—No preliminary medication was used in 152 (52.9 per cent.) of the cases; among these bronchopneumonia developed in 1.3 per cent.; satisfactory anesthesia was obtained in 80.2 per cent., and death occurred in six tenths per cent.; but I did not consider the anesthetic responsible. Of the cases in which morphine only was given bronchopneumonia developed in 1.5 per cent.; satisfactory anesthesia was obtained in seventy-three per cent., and there were no deaths. Of the cases in which morphine and atropine was given bronchopneumonia appeared in 1.3 per cent.; satisfactory anesthesia was obtained in 79.1 per cent., and death occurred in 2.7 per cent. I considered the anesthetic partly responsible for death in one instance.

Operations on the gallbladder under ether (287 cases).—No preliminary medication was used in 220 cases (76.6 per cent.); among these bronchopneumonia appeared in 0.9 per cent. of the cases; satisfactory anesthesia was obtained in 89.5 per cent.; death occurred in three cases (1.3 per cent.) and I considered the anesthetic responsible in two of them. In the cases in which morphine was given bronchopneumonia developed in twelve per cent.; satisfactory anesthesia was obtained in eighty-four per cent., and death occurred in two cases (8 per cent.), in one of which I considered the anesthetic partly responsible. In the cases in which morphine and atropine was given bronchopneumonia appeared in 2.5 per cent.; satisfactory anesthesia was obtained in eighty-two per cent., and there were no deaths. In three cases atropine only was given; anesthesia was satisfactory in all of them and there were no deaths.

COMPARATIVE RESULTS WITH REFERENCE TO THE LESION ALONE (Table 3)

In cases of duodenal ulcer (560) bronchopneumonia appeared in 3.2 per cent.; satisfactory anesthesia was obtained in 84.5 per cent.; death occurred in 2.1 per cent., in 41.6 per cent. of which I considered the anesthetic partly responsible.

In cases of gastric ulcer (66) bronchopneumonia developed in 4.5 per cent.; satisfactory anesthesia was obtained in 87.8 per cent., and death occurred in 1.5 per cent.; I did not consider the anesthetic responsible.

In cholecystic disease (574 cases), bronchopneu-

monia occurred in 1.7 per cent.; satisfactory anesthesia was obtained in 83.2 per cent., and there was a mortality of 1.3 per cent. In fifty per cent. of the deaths I considered the anesthetic partly responsible. In 344 of the cases cholelithiasis was present; in these cases bronchopneumonia appeared in 1.7 per cent., and satisfactory anesthesia was obtained in 81.9 per cent.; the mortality was 1.7 per cent. In 66.6 per cent. of the six deaths I considered the anesthetic partly responsible. In 230 cases of cholecystitis without cholelithiasis bronchopneumonia appeared in 1.7 per cent.; satisfactory anesthesia was obtained in 85.2 per cent.; death occurred in 0.8 per cent.; I did not consider the anesthetic responsible.

SERIOUS PULMONARY COMPLICATIONS (Table 4)

Statistics based on the entire series.—In thirty-one of the twelve hundred cases, bronchopneumonia followed operation; ether was given in twenty-two (70.9 per cent.) and ethylene-ether was given in nine (twenty-nine per cent.); no preliminary medication was used in twelve cases (39.3 per cent.); morphine and atropine were used in nineteen cases (61.2 per cent.); satisfactory anesthesia was obtained in twenty-two cases (70.9 per cent.); death occurred in five cases (16.1 per cent). I considered the anesthetic partly responsible in four cases.

Pulmonary embolism appeared in three cases; in one the lesion was a duodenal ulcer and the anesthetic ethylene-ether; in the second the lesion was cholecystitis with cholelithiasis and the anesthetic ethylene-ether; in the third the lesion was cholecystitis with cholelithiasis and the anesthetic ether. Satisfactory anesthesia had been obtained in all three cases; no preliminary medication was used in one case; morphine only was used in two cases, and death occurred in one case; I did not consider the anesthetic responsible.

Statistics based on primary lesion.—Bronchopneumonia followed operation in eighteen cases of duodenal ulcer; no preliminary medication was used in five (27.7 per cent.); morphine or morphine and atropine was given in thirteen cases (72.2 per cent..); ethylene-ether was given in five (27.7 per cent.). and ether was given in thirteen (72.2 per cent.). Satisfactory anesthesia was obtained in fourteen (77.7 per cent.), and death occurred in two (11.1 per cent.); I considered the anesthetic partly responsible in each instance.

Bronchopneumonia followed operation for gastric ulcer in three cases; ether was given in all of them; no preliminary medication was used and none of the patients died.

Bronchopneumonia followed operation on the gallbladder in ten cases; ethylene and ether was given in four cases and ether in six cases; no preliminary medication was used in four cases, and morphine and atropine was given in six cases; satisfactory anesthesia was obtained in seven cases, and death occurred in three cases. I considered the anesthetic partly responsible in two.

MORTALITY (Table 5)

Death occurred in twenty-one (1.7 per cent.) of the twelve hundred cases. Most of the deaths occurred in three groups: Group 1 consists of five men and one woman operated on for duodenal ulcer under ether. The proportion of males to females is about what might be expected from the relative numbers in the original group of 280 cases. I considered the anesthetic at least partly responsible for the death of three of the patients. Group 2 consists of five men and one woman operated on for duodenal ulcer under ethylene-ether. I considered the anesthetic at least partly responsible for two of the deaths. Group 3 consists of four men and one woman operated on for cholecystitis with cholelithiasis under ether. I considered the anesthetic partly responsible for three of these deaths.

SUMMARY

The most favorable results in this series, from a viewpoint of anesthesia, postoperative pulmonary complications and mortality, were secured in the cases of gastric ulcer when ethylene-ether was used, and in the cases of cholecystitis without cholelithiasis when ether was given.

The best results, from the viewpoint of anesthesia and the incidence of postoperative pneumonia in duodenal ulcer, followed the preoperative administration of morphine and atropine and ethylene-ether anesthesia.

The net results, from a point of view of anesthesia, postoperative pulmonary complications and mortality, in cases of cholecystitis, whether or not there was an associated cholelithiasis, followed the use of ether without preliminary medication.

Anesthesia was satisfactory in eighty-five per cent. of cases on the average. The relative percentages in the ethylene-ether group and the ether group varied in the different operations. It must be borne in mind that the choice of anesthetic depended, to a varying degree, on the condition of the patient and the personal preferences of the surgeon. Other conditions besides the anesthetic, some of them doubtless unknown, affected the incidence of pulmonary complications and the mortality.

Since the percentage of ether required in the different operations varied so widely, it is impossible to draw general conclusions regarding the comparative value of the two types of anesthetic or the effect of the preoperative administration of hypnotics. What is proved in one type of operation is disproved in another. The absence of bronchopneumonia following operations in the large series of cases of duodenal ulcer (and the smaller series of cases of gastric ulcer) under ethylene-ether without preliminary medication, is no criterion (for the establishment of such a routine in upper abdominal surgery). Closer inspection of the figures for operations on gastric ulcer under ethylene-ether will show that bronchopneumonia did not follow in any case, regardless of the institution and type of preoperative medication. Preferences must be limited by the type of operation and no generalizations can be made. body.

The Clinical Effects on the Gastrointestinal Tract Abnormalities of the Portal Circulation*

J. F. MONTAGUE, M.D., F.A.C.S.
New York, N. Y.

Abnormalities of the portal circulation originating as a result of anatomical deviations are so rarely observed that they may be dismissed with but mere mention of their possible occurrence. It also seems unnecessary to dwell upon the clinical effects of sudden portal thrombosis since the symptoms of that condition are so acutely manifest that it is rarely overlooked. Moreover, both of the foregoing abnormalities of the portal system are relatively well recognized and understood, the one by anatomists, the other by surgeons. There exist, however, a large and poorly defined group of clinical pictures which apparently have not yet advanced beyond the empiric stage of recognition, comprehension and symptomatic or placebo treatment. It is toward this group of conditions that I wish to draw your attention and submit for reflection a correlation of some of the abundant experimental and clinical materials available. The logical procedure in my discussion is admittedly sketchy and indeed the supporting data abbreviated to mere mention, yet this must necessarily be the case in consideration of the limits of time and the impropriety of giving here detailed data which can be easily reached in less crowded moments.

In order to more clearly comprehend deviations from the normal state of affairs I trust I will be permitted to recall to your mind the fact that the portal vein is the ultimate of a series of junctures of the various smaller veins which drain the venous blood from almost the whole of the abdominal and pelvic parts of the alimentary canal and its glandular accessories, the pancreas, liver and spleeen. Thus the portal system drains all the venous blood arising from the alimentary tract from the cardiac end of the stomach to the terminal portion of the rectum. Normally, therefore, there is a constant flow of blood from almost the entire gastrointestinal tract toward the right side of the heart through the radicals of the portal vein.

To come now to the deviations from normal portal circulation we find that the commonest abnormality is a functional one evidenced as a tendency toward obstruction. By this is meant an interference with the normal flow of blood from the gastrointestinal tract toward the right side of the heart. It will be noted that this obstruction is mentioned as a functional one rather than an anatomical one since in the instances I purpose to discuss there are but few permanent morphological changes involved. The abnormalities, therefore, are of function rather than of form, and it is perhaps for this reason that they have consistently escaped detailed notice and consideration at the autopsy table. The effect, however, is in many respects closely analogous to what would be produced by certain structural changes in the portal channels. An interference in the onward flow of venous blood in the portal channels naturally results in an increase in portal blood pressure since there occurs incident to and accompanying this, a true hemic plethora in the portal vessels. The superfluous blood volume entailed in such a plethora is distributed in an approximately uniform manner throughout the entire portal venous tree. In the majority of instances the causes at work are of such a nature as to make this portal plethora a fairly permanent condition. Such a state of permanent local plethora is, of course, one of chronic passive congestion, and it is this fact that I wish to emphasize.

All of the foregoing is, of course, a matter requiring no demonstration of proof at this point since it is widely accepted by students of pathological physiology. The best known clinical results of this

*Read before the Section on Gastroenterology and Proctology at the Dallas Meeting of the American Medical Association.

state of affairs arise from the attempt on the part of nature to remedy the embarrassment of normal function produced. Thus an attempt at collateral circulation is made and at three points, i. e., via the esophageal veins, the abdominal veins and the hemorrhoidal veins. This readjustment is in many instances successfully accomplished and the patient then presents the classical symptoms of portal obstruction, i, e., esophageal varices, hemorrhoids and caput Medusæ. While from a didactic point of view the discovery of this condition in a patient is of value in teaching collateral circulation, yet it is scarcely a matter of justice to the patient to await the development of so complete a train of pathology. I am certain that no physician ever waits deliberately to see these symptoms arrive at a classical stage, yet by ignorance of the preclassical indications of approaching portal plethora as much injustice is wrought as if it were deliberate. It, therefore, should be our endeavor to perceive and if possible remedy this state of portal plethora long before it becomes a classical picture of obstruction. This in brief is the object of my discussion.

As has been stated, perhaps the best known result of portal obstruction is the production of hemorrhoids, yet it is an extremely narrow and erroneous view to assume that the production of hemorrhoids is the first chief or only result of this circulatory disorder. That this view should arise is probably explained by the fact that varicosities of the hemorrhoidal veins are exceedingly prone to traumatic injury and more so than similar varicosities elsewhere along the alimentary tract. Owing to at least a partial cerebrospinal sensory nervous supply they frequently give subjective evidence of their presence. Then, too, their ready accessibility to examination renders them more likely of discovery than other analogous lesions higher along the gastrointestinal tract. However, sight must not be lost of the fact that portal plethora exists in portions of the portal vascular tree other than the hemorrhoidal veins, and that its effect is felt on the entire portion of the gastrointestinal tract drained by this system. This effect, however, owing to the sympathetic sensory nervous supply gives far less subjective manifestation and is chiefly denoted, though vaguely, by the definite clinical symptom groups previously alluded to: i. e., as intestinal indigestion, flatulence, constipation, mucous colitis, and other conditions depending upon the portion affected.

I realize that the foregoing is a rather broad assertion as to the rôle that portal plethora plays in the production of the particular clinical conditions mentioned, and feel that a more detailed explanation of what I consider the mechanism of their genesis, should be stated.

The first and most obvious effect of portal plethora is the mechanical distension of the veins and venules which proceeds in many instances to a point where the limit of elasticity is exceeded in the venules and varicosities develop, or in less fortunate cases actual rupture of these structures occurs and is noted clinically as hematemesis, melena, and bleeding hemorrhoids. Aside from this effect, the mechanical distension of the venules limits to no small degree the motility of the stomach and intestines, thereby favoring stasis of the intestinal content. One other effect noted which is to a large degree mechanically produced, is the enlargement of the liver and spleen by the increased blood volume.

More important, however, and decidedly less obvious than the mechanical feature of increased blood volume incident to plethora, is the decided alteration in the chemical qualities of the blood. That this fact is of utmost importance must be evident when we realize that the viscera under consideration, i. e., stomach, intestines, pancreas, liver and spleen, are essentially glandular structures. While it is true that they have other functions, I believe it will be admitted in view of the myriad of glands present that at least the stomach and intestines are predominantly glandular in nature. They have for their function the manufacture of various digestive ferments. This is an extremely delicate physiological process and one which requires for functional efficiency the best possible circulatory support. In portal plethora we have a marked anoxemia, i. e., a condition of insufficient aeration of the blood. The waste products, notably carbon dioxide, are relatively increased, and the restorative elements, notably oxygen, are considerably decreased. Hence it is apparent that when a state of chronic passive congestion such as is present in portal plethora exists, there naturally follows a widespread and serious disturbance in glandular function. Since the processes of digestion are intimately dependent upon the enzymes that these glands elaborate any diminution or alteration in the character of the enzymes is certain to be followed by maldigestion if not actual indigestion. Any marked decrease in digestive function is certain to cause a corresponding increase in that type of digestion termed by physiologists as supplementary digestion. By this is meant the fermentative and putrefactive processes normally affected by the bacterial inhabitants of the intestine in the foodstuffs modified by the digestive secretions. If by the term "intestinal indigestion" we imply the above described process then our term is quite correct, though I fear that such a train of reasoning is not always employed before allotting that diagnosis. It is my opinion that many cases of socalled flatulence are to a great degree explainable upon the basis of these factors.

As to the rôle that portal plethora plays in the production of "constipation" I call attention to the fact that physiologists today attach much importance to the influence of the rhythmic contractions of the intestinal musculature in driving both the venous blood and lymph through the portal channels toward the right side of the heart. Inasmuch as a condition of anemia induces a relaxation of muscular tissue it can be readily seen that a vicious circle is established in which the relaxation of the intestinal muscle tissue increases the plethora which in turn induces further relaxation. With such a state of affairs it is little to be wondered at that constipation and distension occurs. If an additional factor were needed to prove the potency of portal plethora in producing these conditions it could easily be found in the nervous disturbances which ensue upon any such disorder of circulation. It seems highly probable that the function of the plexuses of Meissner and Auerbach are disturbed not only by the mechanical distention

involved but also by the abnormal chemical qualities of the blood. Owing to the delicacy of nervous tissue such effects are chiefly early and rapid responses which are supplemented in a short time by the more lasting glandular disturbances already noted. However, the physiological theories of the nerve regulation of intestinal movements are still so indefinite and fragmentary that their further mention here would cloud rather than clear the issue.

To this point we have noted principally the effects of these deviations in normal portal circulation upon the structures of the alimentary tract, but it must be selfevident that these same conditions also have an effect similar in nature upon those glandular accessory structure of the alimentary tract that share with the stomach and intestines blood supply from the same source, namely, the portal system.

As to the clinical effects of portal plethora upon the spleen, little is known other than that an enlarged spleen arises from the congestion involved. This is chiefly produced mechanically by the increased blood volume in the tributaries of the splenic vein, and because of the locally increased venous blood pressure. Since the spleen has long been and still is an enigma to physiologists, it is difficult to more than conjecture what the effects of disturbance in its not too well defined functions are. It is, however, generally agreed upon that the digestive power of the gastric juice is to some extent dependent upon the functional efficiency of the spleen. Since chronic passive congestion of the spleen interferes with this efficiency, it naturally follows that one of the contributory factors to indigestion occurring in portal plethora is this functional impairment of the spleen. That this organ has some function relative to blood formation and more particularly to blood cell destruction, has been definitely established. In view of the uncertainty of its exact function, it is perhaps unwise to hazard a surmise as to the clinical effects portal plethora has on this function, yet it seems not unreasonable to suppose that the cause of some of our hemic disorders, particularly polycythemia, might be found in portal plethora.

The pancreas is also profoundly affected by chemical and mechanical abnormalities incident to portal plethora and in a manner similar to that outlined previously in respect to the other digestive glands its function is impaired. The clinical observation corresponding to such an impairment is partly a socalled intestinal indigestion and partly various alterations in the fecal content incident to this:—as such may be mentioned steatorrhea or fatty diarrhea.

The effect on the liver is fairly well known as the nutmeg liver of chronic passive congestion is by no means a post mortem rarity. The disturbances in function which this condition causes in life, are dependent upon the functions of the liver, and these too are but incompletely known. Certainly a most natural result are disturbances in biliary secretion with attendant effect on digestive processes.

Thus far we have touched upon the mechanical and chemical features of portal plethora in so far as they affect the circulation of blood. There is, however, another factor besides the simple matter of disturbance in hemic circulatory function. One cannot have a chronic passive congestion without disturbing to a very serious extent the lymphatic circulation and this is, of course, a considerable factor when the intestines are concerned. That the alimentary mucosa is one vast absorptive area is apparent upon a little reflection. The physiological result is not only a local increase in the amount of lymph, but the marked increase in the mucin producing powers of the various glandular structures, particularly throughout the large intestine. This hyperactivity of mucin producing glands, combined with a certain amount of lymphatic transudation into the bowel incident to decreased absorptive powers, combine to produce an abnormal amount of mucus, and this is noted and known clinically as mucus colitis, or later, when the discharge is more largely pure transudate, as one of the diarrheas of unknown etiology.

To this point we have been speaking of complete portal plethora, since, indeed, it is the commonest form. The reason for this may be readily appreciated when we recognize that by this discussion we view at a glance what any partial effects may be. Thus, if obstruction originates by reason of disorder of the right side of the heart all of the various structures along the portal channel distal to this point will be affected in a varying degree, dependent upon the efficiency with which collateral circulation is established. If, however, obstruction is of a more limited nature, such for instance as is produced by the pressure of a pregnant uterus upon the inferior mesenteric veins, naturally the chief effects noted are limited to the area supplied by those branches.

This brings us to the matter of specific causative factors, and an analysis of these and their relation to the train of events hitherto described, serves the double purpose of stating them and of putting to a practical test the accuracy of observations made.

Beginning with the keystone, we find that the condition which is most extensive in its effects is that in which the return of blood through the portal system is impeded by back pressure resulting from chronic valvular disease of the heart. These effects are not only noted in tricuspid regurgitation which is only occasional but more frequently in that relative insufficiency often secondary to lesions of the valves on the left side, particularly the mitral. Thus Osler says, "in some cases of mitral disease, stenosis and insufficiency may reach the stage where all the symptoms are due to secondary changes in the liver." Moreover, in cardiac insufficiency the leading symptoms are "anorexia, indigestion, flatulence, constipation, diarrhea, abdominal pain, and hemorrhoids."

Not only in chronic valvular disease of the heart but in every condition leading to venous stasis in the right heart, the effect is felt in the veins of the portal system. Thus in emphysema, cirrhosis of the lung, and in instances where intrathoracic tumors are present, mechanical congestion occurs, "gastrointestinal catarrh is usually present, and hematemesis may occur. Ascites, slight jaundice, and clay colored stools may also occur." I am of the opinion that the tympanites not infrequently observed in lobar pneumonia is also the result of its potency in disturbing normal portal circulation. In passing we might note Osler's comment, "in certain forms of heart disease in chronic emphysema of the lungs, we may have a

polycytemia or erythema of from seven to thirteen millions red blood cells, and this is accompanied by constipation, hemorrhages from the mucous membranes and an enlarged spleen."

To come lower in the portal venous tree, we find that in cirrhosis of the liver, syphilis of the liver or where the radicals of the portal veins have been invaded by cancer "the patient may first come under consideration for dyspepsia, hematemesis, or slight jaundice." "Later there is to be noted chronic gastric catarrh, irregularity in bowel function, occasionally gastric hemorrhage, and frequently melena, while the spleen is usully enlarged enough to be distinctly palpable."

When we come to the individual branches of the portal vein, we find that symptoms of partial obstruction and local venous plethora may occur as the result of the mechanical extrinsic pressure of a tumor, such as fibroids, an ovarian cyst, or even the pregnant uterus upon certain of these veins. Adhesions may act in a similar manner. Thrombosis or adhesive pylephlebitis is the usual intrinsic cause of partial obstruction. The effects of such obstruction are, of course, more limited than a similar obstruction occurring higher in the vascular tree, and are moreover more capable of being eventually remedied through the agency of collateral circulation.

CONCLUSIONS

I believe the foregoing justifies the following general conclusions:

1. Hemorrhoids are neither the first, chief nor only effect of portal plethora.

2. Plethora in the portal system exerts its effects over the entire portal venous tree. These effects are: a, mechanical upon the blood circulation inducing distention or rupture of the venules, visceral enlargements and a tendency to limit intestinal motility. b, Mechanical upon lymphatic circulation inducing the transudation of unabsorbed lymph and decreased absorptive power of the intestinal mucosa. c, Chemical upon both blood and lymph, causing alteration in the character of glandular secretion and exerting a depressor effect on muscle tissue with corresponding adverse effects on intestinal motility.

3. By virtue of the mechanical and chemical effects noted portal plethora is exceedingly influential in the pathogenesis of clinically vague gastrointestinal disorders such as intestinal indigestion, constipation, flatulence, mucous colitis and diarrheas of unknown etiology.

4. The injustice of a blanket diagnosis should not be made in the instance of such disorders until they are carefully analyzed to exclude the presence of the factor of portal plethora.

A Statistical Study of the Diagnostic Value of Anacidity*

HOWARD R. HARTMAN, M.D.
and WILLIAM W. SAGER, M.D.
Rochester, Minn.

The present study was undertaken with the purpose of studying the diagnostic value of anacidity. Much work has been done since 1879 when van der Velden in Russmaul's Clinic discovered that there is no free hydrochloric acid in the gastric contents of patients suffering from carcinoma of the stomach. The purpose of this early work was to find the percentage of cases in various diseases showing anacidity. We have approached the problem in another way. In selecting the cases for analysis, anacidity was the only factor considered, and we noted the relative frequency of occurrence of various diseases. It is apparent, on a little consideration, that a statistical study made in this manner will give different percentages for different diseases, from one in which the method of study has been the determination of the frequency of occurrence of anacidity in each disease. The percentages worked out in this manner should be almost as accurate as the finding of anacidity in gastric analysis.

Four hundred ninety-two cases of anacidity were collected, in which the method of gastric analysis was the fractional method of Rehfuss. A small percentage only were checked by repeating the analysis. In a study of this nature, however, this will have but little relative effect, as all will be affected alike (with one exception which will be discussed later), and the percentage error in each group would be about the same. Some difficulty arose from the fact that in many cases there were several diagnoses. In such instances, with the exception of malignant conditions, gallbladder disease and pernicious anemia, the case was placed under the diagnosis which explained the symptoms for which the patient came to the clinic (Table 1).

TABLE 1

VARIOUS DISEASES IN 492 CASES OF ANACIDITY

Diagnosis	*Cases*
Carcinoma of the stomach	93
Questionable carcinoma of the stomach	3
Malignant tumors (extragastrict)	8
Cholecystitis	89
Neurosis	87
Pernicious anemia	57
Secondary anemia	12
Anacidity alone	49
Peptic ulcer	13
Goiter	9
Hypertrophic arthritis	7
Syphilis (four cases of gastric syphilis)	6
Questionable syphilis	1
Entamebiasis (Entameba histolytica)	5
Cardiac diseases	5
Hypertension	5
Tuberculosis	5
Cirrhosis of the liver	3
Appendicitis	4

*Submitted for publication, June 2, 1926.

Diagnosis	*Cases*
Empyema	2
Cardiospasm	2
Hypertrophy of the prostate	2
Lymphatic leukemia	1
Duodenitis	1
Procidentia of uterus	1
Pneumonoconiosis	1
Cervical polyp	1
Ulcerative colitis	1
Neuromuscular pain	1
Diabetes mellitus	1
Chronic nephritis	1
Toxic pruritis	1
Hay fever	1
Chronic catarrhal gastritis	1
Chronic mastitis	1
Postinfluenzal debility	1
Bilateral polycystic kidneys	1
Diarrhea (Balantidium coli)	1
Nicotinism	1
Sclerosis of the central nervous system	1
Indeterminate	7

Table 1 suggests the wide distribution of anacidity. It is probable that anacidity was incidental and bore no relationship to the patient's disease except when it was associated with the same disease more than once. However, as the primary cause of anacidity is not known no disease can be excluded.

Carcinoma of the stomach was more frequently associated than any other disease. Of the ninety-six cases, three of which were questionable, sixty-four were inoperable. There were eight cases of malignant disease in other parts of the body: epithelioma of the bladder, carcinoma of the pancreas, carcinoma of the gallbladder and liver, carcinoma of the thyroid, hypernephroma, melanoepithelioma of the foot, epithelioma of the lower eyelid, and Hodgkin's disease, one case each. There is a 20.53 per cent. chance of malignancy in a case of anacidity, an 18.11 per cent. chance of malignant disease of the stomach, and a thirteen per cent. chance of the carcinoma of the stomach being inoperable. It is found, on close analysis of the figures, that 105 cases of anacidity occurred before the patients were forty years of age. This raises the percentage chance after forty to twenty-three for malignant disease of the stomach and twenty-six per cent. for malignant disease of some other part of the body. The chance of malignancy in patients under forty in this series is 4:105. The site of the malignant growths of the stomach was not investigated, as one of us (Hartman), in a study of 551 cases of carcinoma of the stomach, found that situation influenced the percentage of anacidity very little. Anacidity was found in about half of his cases.

For the purpose of comparison 420 cases were studied in which the free hydrochloric acid varied from four to twenty. In this series seventeen cases of malignant disease were found. Twelve were carcinoma of the stomach. The remaining five were: multiple, malignant lesions of the abdomen, carcinoma of the umbilicus, carcinoma of the esophagus, carcinoma of the transverse colon, and abdominal carcinomatosis. In other words, carcinoma of the stomach occurs in 3.1 per cent. of the cases in the presence of small quantities of free hydrochloric acid.

Eighty-nine of the 492 cases of anacidity were associated with cholecystitis (18.11 per cent.). Hurst and others believe that there is a direct relationship between anacidity and disease of the gallbladder and appendix. The difficulty, as pointed out by Bennett, is to determine which appears first: appendicitis, cholecystitis, or anacidity. In eleven of the eighty-nine cases there were stones, in one there was empyema of the gallbladder, and in one the diagnosis was questionable.

Eighty-seven were cases of various functional nervous diseases, in forty of which no organic abnormality was noted other than the absence of free hydrochloric acid. In each of the eighty-seven cases the nervous condition explained the symptoms. The question of the value of repeated gastric analysis arises here, and there is no doubt that the gastric contents of a small percentage of these patients would have shown free acid on repeated analysis, as it is well known that complete suppression of hydrochloric acid may be caused by some nervous influence, such as fear of the introduction of a stomach tube, migraine, or headache at the time of intubation.

Pernicious anemia was found in fifty-seven cases (11.57 per cent.). Faber pointed out that anacidity may precede the other symptoms of this disease. He noted anacidity ten, eight, and four years before death from pernicious anemia. This should be given consideration in evaluating anacidity. Hurst attributes the anemia to an intestinal infection resulting from lack of hydrochloric acid in the stomach to sterilize the contents before they enter the intestine.

Forty-nine cases were found in which the only pathological condition noted was absence of hydrochloric acid.

Only four cases of appendicitis were noted, but the total number of cases of frank appendicitis treated at the clinic is relatively small.

Thirteen cases of peptic ulcer were found. Of this group four were questionable and in two gastroenterostomy had been performed.

The seven cases of syphilis included one in which the diagnosis was questionable. Four were definitely proved to be cases of gastric syphilis.

It would prolong this paper unduly to discuss any of the remaining cases. The diagnoses in these cases were exact, and the table gives the detailed information.

CONCLUSIONS

1. The chances for and against the presence of pernicious anemia, gallbladder disease, or carcinoma, in a case of anacidity, are about even; the chances of either pernicious anemia or carcinoma being present are about one in three.

2. Carcinoma is rare when free hydrochloric acid is present.

The Incidence and Prognosis of Hemorrhage as a Complication of Gastroduodenal Ulcer*

SYLVAN D. MANHEIM, M.D.
New York

The incidence of hemorrhage as a complication of gastroduodenal ulcer varies considerably in medical statistical literature. Most of the figures quoted are based on a study of ward or hospital cases, omitting the vast number of ambulatory ulcer cases treated in the clinic or office. It must, therefore, be remembered that any quoted statistics are usually based on the study of the more serious and restricted group of cases coming to the wards of a hospital for treatment.

By hemorrhage is meant gross bleeding, such as the vomiting of bright or dark red blood or the passage of numerous black tarry stools, together with the clinical signs of bleeding as weakness, pallor, rapid pulse, etc.

The actual frequency of hemorrhage in gastric and duodenal ulcer can hardly be stated with a more than a fair degree of accuracy. Paterson stated that hemorrhage occurred in at least two thirds of all ulcer cases and that it was severe or recurrent in thirty per cent. of them. Osler quotes statistics of the University College Hospital, where the percentage was eighty-four and from the Royal Victoria Hospital where it was sixty per cent. These figures probably include cases with occult bleeding. More recent combined statistics from various sources place the incidence of gross hemorrhage at about twenty-five per cent. Thus, the report of Eggleston, in a study of five hundred cases of ulcer, states that copious hemorrhage occurred in nineteen per cent. W. J. Mayo reports hemorrhage as having occurred in seventeen per cent. of gastric ulcer cases and fifteen per cent. of duodenal ulcer cases.

BASIS OF STUDY

The following report is based on a study of 426 cases of gastroduodenal ulcer treated on the medical wards of Mount Sinai Hospital between the years 1915 and 1925 inclusive. The cases were selected ones, taking only those in which either the x ray findings were positive for ulcer or the clinical diagnosis at least fairly certain.

The incidence of hemorrhage in the duodenal group was forty-eight out of 246, or 19.5 per cent. In the gastric group it was fifty-three out of 180 or 29.5 per cent. Of the entire series the incidence of hemorrhage was 23.7 per cent.

Bleeding from ulcer may occur at any age, but is most common between the ages of thirty to forty years. In this decade there were thirty-one cases of hemorrhage of which fifteen were duodenal and sixteen gastric (Table No. 1).

In this study the incidence of ulcer was found to be far greater in men than in women. We found gastroduodenal ulcer in 361 males and in sixty-five females—a proportion of five to one. However, we see that though ulcer is far more common in men than in women, the incidence of hemorrhage is by far greater in the women (Table 2).

TABLE 1

DUODENAL ULCER

Age	*Total Cases*	*Hemorrhage*
10-20	6	2
20-30	60	12
30-40	81	15
40-50	55	8
Over 50	44	11

GASTRIC ULCER

Age	*Total Cases*	*Hemorrhage*
10-20	4	6
20-30	33	8
30-40	52	16
40-50	40	11
Over 50	51	12

Thus, in the duodenal group, hemorrhage in the female was 2.3 times more common than in the male, while in the gastric group hemorrhage was only 1.8 times more frequent in the female than in the male.

As regards occupation, it is unlikely that business or occupation plays any rôle. Trauma has been described as a causative factor in gastric hemorrhage. It is undoubtedly an important one. A blow or fall on the abdomen may cause a severe hemorrhage. Eusterman in a recent article recounts from his experience several varieties of trauma or violent exercise which caused hemorrhage from ulcer.

TABLE 2

DUODENAL ULCER

Age	*Males*	*Hemorrhage*	*Females*	*Hemorrhage*
10-20	5	1	1	1
20-30	50	12	10	1
30-40	76	12	5	1
40-50	51	6	4	4
Over 50.	41	8	3	2
Total	223	39—17 per cent.	23	9—39 per cent.

GASTRIC ULCER

Age	*Males*	*Hemorrhage*	*Females*	*Hemorrhage*
10-20	2	2	2	2
20-30	20	4	13	4
30-40	42	10	10	7
40-50	31	7	9	4
Over 50.	43	11	8	2
Total	138	34—24 per cent.	42	19—45 per cent.

Hemorrhage may also occur in the course of an ulcer without any previous exertion. We may see hemorrhage as occurring frequently as the first symptom of an ulcer. A large number of these cases had numerous tarry stools as their first indication of any gastroduodenal disease.

Symptoms.—The hemoglobin reading as a prognostic sign is not a very satisfactory one. An accurate chart of the daily blood pressure readings gives far more information as to the progressive changes taking place within the vascular system. The change in hemoglobin denotes a qualitative difference in the dilution of the blood, while the blood pressure is an

*From the Medical Service, The Mount Sinai Hospital, New York. Read before The Clinical Conference of the Mount Sinai Hospital, March, 1926.

indication as to the quantitative change in blood volume. The hemoglobin drops slowly, but progressively, for several days. The lowest drop noted in our series was to twenty per cent. hemoglobin. The average hemoglobin reading was thirty-five per cent. (Sahli) and even at this figure the patients were fairly comfortable. The low point of the hemoglobin is usually reached on the fourth or fifth day after the hemorrhage.

Not so with the blood pressure. With the occurrence of hemorrhage there is a quick and continuous drop in blood pressure until the bleeding ceases. The blood pressure may fall very low, and in one case the systolic pressure was registered as low as 55, the patient remaining fairly comfortable. As a guide to the extent and cessation of the hemorrhage, the blood pressure is a more delicate test than the fall in hemoglobin. When the bleeding has ceased the blood pressure shows a gradual and steady rise, while the hemoglobin falls or remains low for several days (chart).

Prognosis.—The prognosis as to life in gastric and duodenal hemorrhage is good. Contrary to many preconceived notions, patients rarely die of hemorrhage. Nielsen in a careful and systematic followup study of ulcer cases, reports one death in 182 cases followed for from two to nineteen years; while Eggleston reports one case of fatal hemorrhage from bleeding ulcer in a series of cases covering twenty years. Paterson quotes four series totalling 1243 cases with a mortality of 3.8 per cent.; while Hurst reports six hundred cases from Guy's Hospital with a mortality of 2.5 per cent.

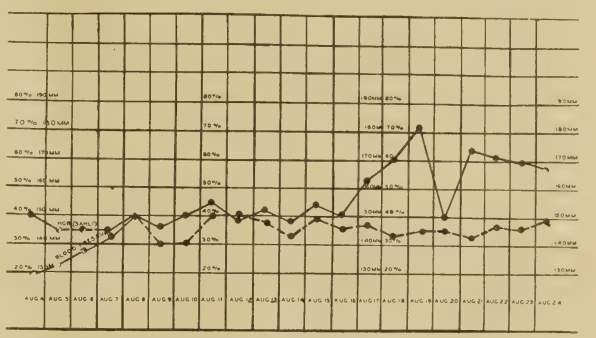
In this series of 426 gastric and duodenal ulcer cases from the medical wards of Mt. Sinai Hospital 101 patients had severe hemorrhage. Seven of these cases (in the early years) were transferred to the surgical side for immediate operation; five of these seven died. The remaining ninety-four were treated medically. In this latter group there were four deaths, proven at autopsy to be peptic ulcer cases. This is a mortality rate of 4.2 per cent. of the bleeding cases. Omitting the seven cases transferred to the surgical wards, we have four deaths out of 419 ulcer patients treated medically; a mortality rate of 0.9 per cent. of the total ulcer group. These figures agree with other statistics; thus Bevan reports ninety-five per cent. recovery from hemorrhage and Payr reports ninety-seven per cent. surviving under medical treatment.

What does the surgical treatment of hemorrhage offer? Surgeons today are agreed that the bleeding ulcer patient with his acute anemia and more or less collapse, is at the time of the hemorrhage not a desirable surgical risk. The surgical mortality rate in these cases is extremely high. Surgical treatment, if instituted at all, should not be carried out until one month or more has passed since the hemorrhage.

Shall the patient with chronic recurring hemorrhages be operated upon? In this series of cases none of those with repeated hemorrhages died. The fatal cases all occurred as a result of the initial brisk hemorrhage. These are cases of profuse hemorrhage, with rapid and fatal termination, before medical or surgical treatment could have checked its course.

Does gastroenterostomy protect the patient with a chronic condition from a recurrence of the hemorrhage? Balfour noted that hemorrhage occurred after operation (gastroenterostomy) in thirteen per cent. of cases with a history of previous hemorrhage, and in 0.9 per cent. of gastroenterostomy cases without a previous record of hemorrhage. Eusterman reports a recurrence of hemorrhage in twenty-five per cent. of cases following operation; while Eggleston reports a recurrence in eleven per cent. In this series eight patients had a recurrence of hemorrhage in from two to eight years following a gastroenterostomy. Gastroenterostomy then, is not the operation of choice. Excision of the ulcer, with its persistence of the presence of free hydrochloric acid, leaves the patient open to a recurrence of the ulcer. Subtotal gastrectomy then, is the only logical operation, though the mortality rate is higher than for the type operations previously mentioned.

I do not mean to convey the impression that an



HEMOGLOBLIN & BLOOD PRESSURE

ulcer case that has bled should never be operated upon. Under certain conditions such as chronic progressing anemia from repeated hemorrhages, persistent pain or pyloric obstruction, surgical intervention is absolutely necessary. I do maintain, however, that hemorrhage alone, or the fear of a future hemorrhage, with no other alarming or incapacitating symptoms, is not an indication for surgical intervention.

Medical treatment offers, in my opinion, the safest and most promising results. We must, for the present, be resigned to the initial loss of a certain number of bleeding cases and should consider ourselves fortunate in being able to keep the mortality rate as low as it is with medical treatment.

As part of our general followup of ulcer cases, we have paid special attention to the remote effects of hemorrhage upon the life history and ultimate fate of ulcer cases subject to this complication. Of the ninety-four cases of bleeding ulcer, we are able to report on the end results in thirty-six patients. Most of them have been followed for from one to four years and some for periods up to nine years; five had had multiple hemorrhages before coming under treatment and observation.

Of the thirty-six cases followed: nineteen or fifty-three per cent. have remained well since their stay in the hospital. Seventeen or forty-seven per cent. have had recurrences of symptoms. Of the seventeen cases with recurrent symptoms: five are still under medical treatment. Four have had recurrent hemorrhages. Eight have been operated upon. Of the eight patients operated upon: six are well. One had recurrent postoperative hemorrhages. One has a recurrence of symptoms.

There were no deaths in the cases of recurrent hemorrhages which occurred during the years of followup observation. This is a most important point. It corrects the impression, rather current, that a gross hemorrhage is likely to be followed in subsequent years, by later more severe and probably fatal exsanguination. Our own conclusion therefore agrees quite in detail with that of Nielsen, who, in a far larger series and more prolonged followup, also came to the conclusion that recurrent hemorrhages that end fatally are extremely uncommon. A strong argument for the operative treatment of bleeding cases is thus unseated.

In fact, we noted recurrence of hemorrhage in only four cases out of thirty-six cases followed for these years. This is an incidence of only 11.1 per cent., a figure which is lower even than the incidence of hemorrhage in ulcer cases in general. It would thus appear that, contrary to all expectation, a case that has once had a severe hemorrhage is relatively less likely to a recurrence than are ulcer cases as a group.

One of the patients of the thirty-six cases of hemorrhage was subsequently operated for acute perforation. This is an incidence of less than three per cent., which again is approximately that of perforation of ulcer in general. It would therefore seem incorrect to conclude that hemorrhage predisposed in any way to subsequent perforation.

Again, we note that the percentage of cure in ulcer cases that have bled is almost as good as in ulcer cases as a general group. In our own published followup series (Einhorn and Crohn), of a group of general gastroduodenal ulcers observed for one to four years, we reported sixty per cent. as cured. This figure agrees well with the curability of ulcers after hemorrhage, the slight difference between sixty per cent. for general ulcer cases and fifty-three per cent. for the hemorrhage group, being inconsiderable.

Although one should realize that a followup study of gastroduodenal hemorrhage should be based on very large groups of cases; nevertheless we feel justified in coming to the following conclusions:

1. The incidence of severe hemorrhage from gastroduodenal ulcer is about twenty-five per cent.

2. The mortality rate from hemorrhage is about four per cent. of the bleeding cases and approximately one per cent. of ulcer cases in general.

3. Surgical treatment of gastroduodenal hemorrhage cases does not lower the mortality rate.

4. Hemorrhage does not seem materially to alter the life course of an ulcer.

5. The percentage of cures in hemorrhage cases is about the same as in ulcer cases as a group.

6. The remote danger from hemorrhage has been overstated. The argument that one hemorrhage may at any time be followed by another and possibly fatal exsanguination is not confirmed by the facts of this followup.

7. The likelihood of perforation is no greater in bleeding cases than in ulcers as a general group.

473 West End Avenue.

Gallstones*

EDWARD L. KELLOGG, M.D., F.A.C.S.

New York

The purpose of this paper is to review the subject of cholelithiasis, to consider the complications and to discuss the management of the disease.

The earliest note of concretions in the liver occurs in the writings of a Greek physician, Alexander Trallianus, whose book, after having been lost for upwards of a thousand years, was found by Stephanus and published in Paris in 1548. He refers to "dried up humors, concreted like stones," and considers them a possible cause of obstruction in the liver.

About 900 A. D. Rhazes, an Arabian, described the stones found in the "gall of the ox, which philosophers call Alcheron," stating that if the substance is ground and drawn into the nostrils, it will promote sharpness of the eye: and in 1602 Gesner recommended it for epilepsy.

Gallstones in the human subject were first described by Benivenius, of Florence, in 1400 A.D. He cites the following case: "A certain noble lady had been suffering for a long time from pain in the liver region and, although she had consulted many physicians, she had not been able to get rid of her malady. For this reason she was pleased to try our aid, together with others.

We met several physicians and discussed at great length what might be the hidden cause of the disease. As happens frequently in doubtful matters, we could not agree, for some supposed an abscess of the liver, others a degeneration of that organ. We, ourselves, believed that the fault was with the covering membrane.

When she, after a few days, during which the illness increased upon her, had departed this life, as we had from certain signs foretold, we procured the opening of the body and there were found small stones differing in shape and color, which had collected in the lower part of the membrane of the liver. Some were round, others angular or quadratic, as position and accident had affected them. Some had red spots, others were distinguished by blue and white ones. By their weight, they had formed of the covering of the liver a small sac, of the length of the hollow of the hand, and of the width of two fingers.

As we believed these to be the cause of death, we judged it vain and useless to dispute on obscure matters."

In 1609 Schenkius gives a grotesque description of the effect of gallstones: "Horrible and stupendous calculi coagulate in the gallbladder, their shape, color, number and wonderful effects producing vomiting, nausea, heaviness, low spirits, tearings of the stomach and hypochondrium, atrophy, tabes, obstruction of the viscera, inflammation, incurable jaundice, sleeplessness, lassitude, sadness, melancholic affections, inclin-

ation to anger, difficulty and heat of urine, lepra of skin, fever, sudden death by a hidden and generally unknown seminary and foment of diseases and symptoms."

In *modern* times, the names of Thudicum (1863) and Naunyn (1896) are connected with the pathology and treatment of the disease.

The surgery was developed largely by Courvoisier in France, Kehr and Langenbeck in Germany, Kocher in Switzerland, and J. Marion Sims in the United States, although in 1618 Fabricus Hildanus performed the first operation for removal of gallstones and in 1743 Petit deliberately carried out the procedure in cases in which the gallbladder was adherent to the abdominal wall. In 1867, Bobbs, an American surgeon, performed cholecystotomy in one stage, and in 1882, Langenbeck did the first cholecystectomy.

The importance of this subject is shown by the statistics of gallstones in seven to ten per cent. of all autopsies and in twenty-five per cent. of persons over sixty years of age.

It is much more frequent in women than men and ten times more common in those who have borne children than in those who are sterile. It is comparatively uncommon in people under thirty but is not a negligible factor in the diseases of early life.

In 1923, the writer reported sixty-three cases of gallbladder disease, collected from the literature, all under fifteen years of age, adding that of a child, aged twelve. Several were among very young children or newborn infants and one was an eight months fœtus.

It is not practicable to separate the consideration of gallstones and cholecystitis, for with the exception of the rare cholesterin calculus, infection always occurs.

The calculi met with in sixty per cent. of the cases are a mixture of cholesterin and bilirubin calcium. The presence of other varieties does not alter the problem.

The specific etiological factors are stagnation of bile, infection, catarrhal inflammation, a deposit of cholestrin and bilirubin calcium.

Biliary stasis is favored by sedentary habits, obesity, infrequent meals, constipation, pressure, adhesions, enteroptosis and pregnancy.

Chronic cholecystis may follow typhoid, chronic infection of the colon, teeth or tonsils. Although streptococci, bacillus coli and the typhoid bacilli are commonly reported, other bacteria are found with sufficient frequency to indicate that the variety of infection is not important. It is essential, however, that its activity be sufficiently attenuated to render it incapable of maintaining an acute inflammation. The bacteria usually reach the gallbladder by way of the blood or lymphatics, first involving the deep layers, rather than the mucosa, and possibly explaining the relative sterility of the bile, although it is known that the concentration of the gallbladder bile discourages the growth of bacteria. (Drennen reports nineteen per cent. of bile infections in one hundred cholecystectomies.)

This offers an argument in favor of cholecystectomy rather than cholecystostomy.

Naunyn taught that the cholesterin content of the bile is constant but McNeer has shown that it varies with the amount in the blood, justifying, in a measure, the discredited theory of cholesterinemia advanced by the elder Austin Flint. But as gallstone patients do not all show hypercholesterinemia, Naunyn's explanation must be accepted, that cholesterin is derived from the mucous membrane of the bile passages, since it is always present in secretions from diseased mucous membranes, in pus and in degenerated epithelial cells.

He admits that a stone, once formed, may grow by crystallization of cholesterin from the bile. Apparently, therefore, both processes are at work. The hypercholesterinemia, normally occurring in pregnancy, explains the predisposition of the parturient woman to gallstones.

The mucus secreted causes the combination and precipitation of bilirubin calcium, which acts as a cement substance.

"The pathological anatomy of cholelithiasis forms the foundation for its diagnosis and treatment" (Kehr).

Stones may remain quiescent in the gallbladder, or cause a recognizable cholecystitis, possibly progressing to acute inflammation empyema or gangrene. The gallbladder may dilate or contract, pericholecystic adhesions form, or perforation occur—suddenly with peritonitis, or gradually with the formation of external or internal fistulæ. (Naunyn collected 384 cases of biliary fistulæ, of which 108 communicated with the duodenum, 184 with the abdominal wall and fifty with the colon. Occasional communication was found with the stomach, urinary tract and thoracic organs.)

The cystic duct frequently becomes obstructed. In the common duct, a stone may cause obstruction with jaundice and cholangitis. Impacted in the ampulla of Vater, it often leads to pancreatitis. Entering the intestines by way of the common duct or fistulous opening, it occasionally causes obstruction.

Complications develop in the stomach and intestines and the absorption of inflammatory products results in arthritis, neuralgia and migraine. Malignancy occasionally terminates the disease. Kehr states that only five per cent. of persons with gallstones have symptoms. Moynahan maintains that, with the exception of the rare cholesterin calculus, symptoms are always present, but may not be recognized. Weile (1) groups the cases as gastrointestinal, hepatic, migraine and masked. Schneider (2) reconstructs the life history of the disease into decades. During the first and second, the development of cholecystitis may be noted, followed by toxic symptoms. During the third and fourth, digestive symptoms become more marked. From the fourth to the eighth decades, advancing local changes and complications are expected. At any time, a stone may attempt to migrate, inaugurating an attack of colic.

Typhoid fever, pneumonia or acute appendicitis frequently precedes the onset of the disease.

The early symptoms are usually obstinate dyspepsia, heartburn, fullness, weight, distention, partially relieved by belching or vomiting and increased by greasy foods with remarkable constancy (Moynahan). There may be a stabbing pain under the right costal margin upon deep breathing. Dull epigastric pain, not relieved by food, is common.

Sherren stresses the irregularity of symptoms, which come and go at intervals and are not so clear

cut as in ulcer, although it is difficult to distinguish the gastrointestinal type from ulcer or appendicitis. Among the toxic symptoms, migraine (sick headache with vomiting) is common and may be the only complaint. Ultimately the symptoms will localize sufficiently to lead to the diagnosis.

Gallstone colic is familiar to practitioners of experience and is seldom wrongly diagnosed. It develops suddenly or is preceded by a sense of uneasiness in the epigastrium or over the lower right ribs.

It may lead to nausea and vomiting and usually terminates suddenly. The attack may come without apparent cause or appear to be caused by exertion or by food. The frequency of biliary colic in the early morning hours when, from the position of the body, calculi in the gallbladder are apt to lie in the region of the duct, is probably due to the physiological contraction of the distended gallbladder.

In analyzing the pain of gallstone disease, it may be possible to differentiate between that of biliary colic and cholecystitis, and to recognize reflex and referred pains.

Murphy is authority for the statement that in seventy per cent. of the cases of obstruction of the cystic duct, pain is referred to the right subscapular region: in ten per cent. to the left subscapular region, and in twenty per cent. to the precordia, sternum and right subscapular regions.

Kehr states that it begins at the right of the eighth to eleventh dorsal vertebra, spreading to the right hypochondrium, from which it radiates to the left hypochondrium, umbilical and hypogastric regions, to the thigh, the right arm and neck.

PAIN

Pain due to inflammation or distention of the gallbladder is usually felt under the right costal margin and is not so severe as that of biliary colic. It may begin suddenly or gradually but as a rule slowly disappears.

Typical examples of reflex pains are those caused by pylorospasm of hyperchlorhdria. Pain referred to the right shoulder and arm, may be the only symptom leading to treatment for neuritis.

It may be referred to the left side of the abdomen, and to the precordial region, simulating angina. Examination will usually reveal superficial sensitiveness in the upper right quadrant of the abdomen, with rigidity of the rectus muscle. The pains that precede or follow an attack of colic, may be misleading when they recur at regular intervals after meals or at night. Intercostal neuralgia is occasionally complained of, involving the ninth, tenth, and eleventh right nerves.

Vomiting, accompanying an attack of colic, may be very violent and persistent, frequently without relieving the symptoms.

JAUNDICE

Jaundice, preceded by colic, is practically always due to stone. Jaundice, without pain, is usually caused by inflammation, or new growth of the ducts, or outside pressure. It is absent in eighty to ninety per cent. of all operative cases (Brewer).

Calculi in the gallbladder or cystic duct do not obstruct the flow of bile, unless the common duct is compressed by inflammatory products, or enlarged lymphatic glands. Frequently, however, a slight icteric tinge of the conjunctiva can be detected.

A stone in the common duct may cause intense jaundice if impacted. When it is small enough to act as a ball valve, intermittent jaundice usually occurs.

Pruritus accompanies intense jaundice and often persists after it has disappeared.

Fever depends upon the inflammatory reaction in the gallbladder or ducts. It is frequently absent, or manifest as a slight rise of temperature, during an attack of colic. In common duct stone with cholangitis, there may be a marked rise of temperature, with chills and profuse perspiration, simulating malarial fever. (Charcot's intermittent hepatic fever.) The temperature chart is characterized by angularity, rather than by curves, and by more or less prolonged periods of complete remission (Murphy).

PHYSICAL EXAMINATION

Of the physical examination, Kehr writes as follows: "Of all methods of diagnosis, palpation is the most important. Many a doctor who has had sufficient practical experience, nevertheless, never learns it, since lightness of hand is lacking in him. The physician should penetrate very gently into the deeper parts with the finger tips, so as to avoid muscular contractions. With bimanual examination we attain the best results. The palm of the left hand is placed on the right side of the patient's back and presses the liver upward, against the curvature of the ribs, while the right hand, resting on the gallbladder region, palpates, gently and cautiously, the diseased parts.

Then frequently appears, what could not be determined by the simpler examination, the egg shaped figure of the gallbladder, or one feels that limited resistance, which is so important for making the diagnosis. If the gallbladder does not reach the lower border of the liver, it will elude the examining fingers, even though distended. Here, the bimanual procedure is often decisive, since with experience, one can demonstrate a painful concentration at a particular spot."

Examination is facilitated by placing the patient in a warm bath, or by giving a few whiffs of chloroform or a small dose of morphine.

With stone in the common duct, tenderness may be found at the Mayo-Robson point (at the juncture of the outer third with the inner two thirds of a line from the tip of the ninth right cartilage to the navel). In simple gallbladder involvement, it is often possible to elicit tenderness at the point of approximation of the fundus of the gallbladder to the abdominal wall, where the outer border of the rectus muscle meets the costal arch (corresponding almost exactly to the tip of the ninth rib) or over the subcostal part of the liver; and on the dorsal surface, beginning slightly to the right of the spine and extending almost to the posterior axillary line, opposite the two lower dorsal and upper lumbar vertebræ, with maximum tenderness over a small area at the right of the twelfth dorsal. Sharp pain may be elicited by pressure on the anterior extremity of the eleventh rib. Chauffard notes tenderness also over the right phrenic nerve, the right shoulder and at the angle of the scapula.

The phrenic nerve tenderness is confirmatory evidence of some value in the absence of thoracic disease.

Historical Medicine

Maimonides' Treatise on Poisons

LOUIS J. BRAGMAN, M.D.
Syracuse, N. Y.

In Virchow's Archives for 1871 (1) a German revision of an unedited Hebrew translation of the original Arabic work of Maimonides on poisons was published by M. Steinschneider. Realizing that this treatise, which according to Garrison (2) was much cited by medieval writers, has never appeared in English, the following rendition (3) from the German was prepared with a view towards making available one of the best known of the contributions of this renowned twelfth century physician (4).

From about the time of 1190, Moses Maimonides was favored with being installed as physician to the household of the Vizier Kahdi-el-Fadhil. The book of poisons was a direct consequence of this exalted position, for in a long dedication in praise of the virtues and acts of kindness of his patron, he quoted a letter that the Vizier wrote to him in the year 1198:

"I have but yesterday thought upon this, that one can be bitten by a poisonous animal, so that before he comes to us and takes the theriac, the poison could have spread and caused his death, especially should he be bitten at night, so that he first comes to us in the morning; further, I have considered that these theriacs which are so hard to prepare are used up on the least occasion, for example, in the case of the bite of a scorpion or a spider, which calls for a theriac of some forty-two substances; therefore I command you to compose a treatise of small size and terse style on the treatment which is to be put into effect in case of a bite; mentioning the methods of cure, the diet, and also a few theriacs which are generally useful for the patient, apart from the two large theriacs which are given when nothing else suffices."

To this flattering commission Maimonides modestly replied:

"I have begun to execute his command, and to write this essay, which I have called the *Treatise of Fadhil.* Without doubt my master is aware that all the ancient and modern physicians have written tracts on this subject, and have handled it in great detail. I have not had the design to present something original, which had not as yet been written about, or which is unique; rather have I made it my purpose to gather together a small number of opinions on the subject which may be of some value."

He further declared his intention of mentioning only the simple and useful remedies, refraining from piling up a great number, which would only be difficult of comprehension. He would emphasize only the most effective ones, and those easiest obtained and prepared. On the subject of the preparation of remedies, he added:

"Doctors often mention a simple remedy which may be very effective against a deadly poison but do not tell how to prepare it or what proportion to use, presuming that the reader is acquainted with these details. On this account I will analyze the preparations in this essay so that one will find it complete in all details. And I will mention only those combined remedies which are easily preserved and are most useful."

He divided his treatise, as will be seen, into two main sections, the first on the bites of snakes and other animals, consisting of some general rules, applications of remedies to the wounds, simple and combined medicines, various means against specific bites, and types of bites in general and particular. The second part deals with the prophylaxis of poisons, rules to be followed in cases of actual or assumed poisoning, simple and combined remedies against poisoning, and rules for those who are unaware of the nature of the poison taken.

And, as he concluded in his foreword, only a few of the ways and means were considered, for the purpose of shortening the treatise, "to which," he piously added, "may God guide us in the proper direction."

SECTION I. CHAPTER 1. GENERAL RULES REGARDING BITES

In case of a bite, constrict the bitten place as tight as possible, so that the poison will not spread throughout the entire body; while this is being done, make an incision with a knife over the same place that was bitten; suck the wound with the mouth and then spit out all that has been sucked in. Rinse the mouth with olive oil or wine and oil before sucking, and anoint the lips with violet oil if it is handy, or if not, with olive oil, for the protection of the one who is to do the sucking. Finally there should be no diseased condition present in the mouth nor any decayed teeth. Some doctors maintain that the assistant should not have partaken of any food, others that instead of being in a fasting state, he should have eaten a little. It seems to me that a state of fasting is more advisable for the victim, but for the one who is to suck the wound it is dangerous, and *vice versa;* for the saliva of a fasting person is beneficial for the healing of wounds, as well as for most virulent wounds. If there should be no one on hand to suck the wound, or if the one who has been so designated proves to be in a weakened condition himself, cupping should be resorted to, either by means of fire or without; the former is more effective in that it combines suction and heat. Immediately following this, the stomach should be emptied by means of a mild emetic; but if vomiting is difficult to provoke, oil and butter can be taken; however, it is advisable to guard against painful vomiting. Promptly after this a strong antidote should be taken, or as a substitute a mithriadic electuary, or one of the special electuaries which are effective against poisons, or if these prove inefficacious, resort can be had to one of the simpler remedies described later on, and taken according to one's judgment. Then apply some remedy, either singly or combined, which will serve to

draw the poison out. After an hour the patient describes his symptoms. If the pain has subsided, and if his color is good, nothing more happens. However, care should be exercised to prevent the patient from falling asleep, for in sleep the bodily heat tends to draw the pus towards the inside of the body, and the poison may thus permeate deeply; if the vital organs should be reached, death will follow; hence under all circumstances prevent him from sleeping. If the tourniquet is painful, loosen it a bit. If the medicine has already passed through the stomach, eight hours being necessary for this, give the patient nourishment in proper proportion for a bitten person. But it is necessary to observe whether the pain of the bite is more severe because of the food; if so, discontinue all previous treatment, kill a young pigeon, split open its stomach, and lay it upon the wound. As fast as its warmth diminishes, replace it with a fresh one. If a young pigeon is not available, substitute a large hen or cock. Above all remember that the application should continue until the pain has disappeared and the poison extracted. If a fowl can not be obtained, pour vinegar on the bite, or prepare a plaster of flour boiled with olive oil; this will ease the pain. Finally, after all these remedies have been employed, and there is no improvement, but rather the condition is aggravated, and the patient becomes weaker, then treatment is necessary which is out of reach of the untrained person. In this case an experienced physician must be summoned, one who is well acquainted with the usual methods of attacking the various symptoms which arise according to the individual temperament of the bitten person.

CHAPTER 2. SIMPLE AND COMBINED REMEDIES WHICH CAN BE APPLIED TO THE BITE

The simple remedies which serve to draw the poisons from the body when applied to the bitten part are mentastrum, basilicon, crocodile fat, pigeon and duck dung, sulphur, asafoetida, goat's dung, green bdellum, table salt, onion, jew's stone; whichever of these can be obtained is powdered and kneaded with honey, from which a paste is prepared and applied to the bite after it has been sucked or cupped; in this manner the poison will be extracted. A similar result may be obtained by means of a paste prepared from the husks of nutgall. The seeds of citrus pitimina, if obtainable, ground and prepared as a paste, make a remarkable specific against the poison of bites, and prevent fatalities.

Combined remedies. Grind together equal parts of onion, salt, and pigeon dung, and apply to the bite. Althea seeds, moist or dry, ground up with vinegar and oil, can also be applied. Stronger poultices: mustard and potash and unslaked lime, in equal parts, combined with pinus cedrus; any one of these should be applied quickly, before the poisons get a chance to penetrate. Another remedy: salt, ashes, figwood or grapevine, and saltpeter, in equal parts combined with vinegar and nutgall husks. Another which Rhazes has proven effective for the pain and the poison consists of serapinum, castoreum, asafoetida, sulphur, pigeon dung, mentastrum, and calamentum, well mixed in equal parts with old oil, and prepared beforehand in order to have a plaster ready in case of emergencies.

In the opinion of the writer strong cinnamon can be used when calamentum cannot be obtained. It is also of value if the mentastrum is to be boiled with vinegar in order to prepare a paste.

All these substances are easily found and are effective in this dangerous condition.

CHAPTER 3. ON RULES FOR SIMPLE REMEDIES WHICH ARE TO BE USED IN THE CASE OF BITES OF POISONOUS CREATURES

Physicians mention many simple remedies which are of value in counteracting the bites of all poisonous animals. Your servant has considered them all, and has become acquainted with those that have a warm nature, but of the cold ones he is only aware of the root of the mandrake. It is not probable, however, that warm or cold means are effective against warm or cold poisons simply because of the similarity in that respect, for the effect of a remedy against a poison does not depend upon the quality (i. e., whether it be warm or cold), but upon its entire nature, with which the physician cannot be wholly acquainted; according to philosophical speculation remedies are effective in the degree of their specificity. Those remedies which are recommended by physicians are wine, water, and vinegar and milk. I believe, however, that first the condition of the patient should be investigated, in those incidences when the species of the animal is unknown. If the patient is feverish, as results from the bite of a snake, the best choice of remedies is milk or vinegar. If the patient is very chilly, as results from the bite of a scorpion, wine should be taken, but if it should be contraindicated, a decoction of anise can be taken, for physicians agree that anise is good for all animal bites. After this general introduction I will speak of those remedies which we have on hand, which are remarkable for their healing power, and which have been handed down by experience as direct remedies. Citron seeds are effective against all poisons resulting from bites. Preparation: Remove the covering of the seeds, powder the kernel, and dilute to the proportion of two drams; Avicenna actually lets it take up two sicla in wine or water. There is no difference between the seeds of the sweet and sour fruit.

Extremely green emeralds, somewhat resembling sapphires, can be made use of; two carats, well ground, are mixed in cold water or wine. According to Ibn Zohr it is beyond all doubt established as a remedy; it antagonizes the poisons, and causes them to be eliminated through vomiting, just as it accomplishes this result for theriac, when this is lacking.

Bezoar is not mentioned by Galen. The bezoar stone, surnamed the animal stone, is shaped like an acorn; it is deep green in color, and is formed through condensation, on account of which it appears in the form of layers. In the East it is said that it is to be found in the tears of the ram; others claim that the gallbladder contains it, and this is true. In regards to the mineral type of the bezoar, this is the stone that is found in Egypt, and that has many colors, and in earlier writings was considered to be wonderful; but unfortunately none of it has been preserved. I have tried all the mineral stones that we have in our locality as remedies against the bite of the scorpion, and they have not helped in the least; I used many of them in a special case with no result. On the contrary the rationale of the use of the animal

bezoar has been established by experience. Preparation: Pulverize with oil on the grindstone, until it lacks an eighth of a scruple to a carat; then part is taken, and part put on the wound as a plaster, and the patient will recover.

The three remedies which have heretofore been mentioned are good against animal, vegetable, and mineral poisons, as has been established by experience, namely, the seeds of citron, emeralds, and animal bezoar. Arak al-Hija, that is, the roots of a plant found in the vicinity of Jerusalem, has been established by experience to be efficacious. It is ground up, dissolved in cold water or wine in the ratio of one to three and a half drams; it has not the strength, truly, of emerald and animal bezoar, yet it is answerable, in general, so that it may be prepared and kept ready on hand. A botanist tells me that this remedy is the root of melilot.

Any kind of tripe, especially hare's, prepared in the proportion of one half dram to one siclus, helps in cases of animal and mineral poisons. Another remedy is Roman spices, one dram powdered and taken in wine. Others are as follows: The plant gafit and its seeds, two drams powdered and taken with wine. Balsam oil, one half siclus with fresh milk. Balsam wood or shrubs, six drams boiled with one half litre water until a third has evaporated, taken warm.

In accordance with all physicians crushed onions is a great theriac against cold poisons, and is also of help against warm. Preparation: Peel the onions, grind them a bit, then take one to two sicla of them. Electuary of ginger up to two drams in warm water. Roots of mandrake powdered and sifted, two drams with one ounce of honey. Powdered cinnamon, two sicla of the powder in cold water. Bitter costus, powdered and sifted, one siclus in wine. Aristolochia longa, in the same form and quantity. Agaricon, and especially algatia, and nuts. Iris, also called gladiolus, powdered, two drams in vinegar or wine. The seeds of parsley or leek, powdered and mixed with wine. Carraway, four drams powdered, in water or wine. Anise, in the same manner. A decoction prepared from boiled river crawfish.

All these remedies are easily obtained, with the exception of balsam oil, which, however, is very easily found in Egypt. Whatever remedy is selected should, as previously mentioned, be taken immediately after vomiting. The patient will also be grateful for a mixture of three ounces of warm honey in an ounce of oil of rose.

All the quantities mentioned are computed for those who can take vigorous remedies, and who are at least twenty years old. For those from ten to twenty the medicines should be diminished proportionately. It seems that no one can recover from a severe bite or sting under the age of ten. Nevertheless that age should be given one quarter of the quantity of the above simple remedies, and one quarter dram to one quarter siclus of the theriacs, according to the opinion of the doctor; one must take into consideration the special temperament and the season.

CHAPTER 4. COMBINED REMEDIES

The most important of these is the large theriac, of which one fourth of a dram to one fourth of a siclus can be taken. Then comes the mithridate, one half to one siclus; then the theriac comprised of four parts, one to four drams. Preparation: myrrh, laurel seeds, serpentaria, gentian, in equal parts, kneaded with skimmed honey in weight threefold all the ingredients; this will provide a single theriac against all poisons. This is the foremost composition used by the ancients.

Rhazes mentions another theriac containing asafoetida, which is worthy of being known. Preparation: myrrh, leaves of dry rue and dry mentastrum, costus, black pepper, and piretrum, one ounce of each, asafoetida, one and one half ounces dissolved in wine; the other ingredients powdered dry and sifted, and all kneaded with skimmed and heat concentrated honey. In warm countries one to two drams are taken, in cold, two to four.

A theriac of nuts is especially valuable, and is satisfactory for ordinary use; and whoever accustoms himself to taking this as a food with his meals, will find that he will be protected against deadly poisons. Its preparation calls for one dram of figs, salt, nuts, and rue. The quantities called for by Galen are four parts of rue leaves, two of nut meat, five of salt, two of dry figs, all macerated together and combined with myrrh. Rhazes prescribes the following: dry, shelled nuts, one part, thick salt, dried rue leaves, of each, one half part, white figs, as much as the rest combined. Divide into little more than the size of a nut, and take a part of that.

Ibn Zohr mentions the theriac of onions, which in his experience had proved curative against the bite of a poisonous animal. Preparation: Peeled onions, four ounces, leaves of parricide, in the vernacular called matrunia, gentian, black, white, and long peppers, and ginger, about an ounce, white mushroom, stichados, of each one half ounce, and opium (if it is damp, rub the wounded part with it), two drams dissolved in wine until soft. Mix the dried ingredients, and knead it all in pure, heat concentrated honey. The dose is one to three drams.

All these theriacs can be taken either in wine or in a decoction of anise, according to choice. The individual dose, ranging between the smallest and the largest, is determined by the age, the severity of the attack, according to the time of the year, and the country. Cold seasons call for warm and vigorous methods, and *vice versa*.

Avicenna mentions a universal theriac of this composition: nigella, harmel seeds, carraway seeds, three drams of each, gentian, round aristolochia, of each one and one half drams, white pepper, and myrrh, of each an eighth, all kneaded with pure, skimmed honey. The dose is one half dram.

Galen mentions a remedy effective against the bites of very poisonous animals as well as for uterine colic. Preparation: extract of hyocyamus and schakran, four sicla of each, castoreum, white pepper, myrrh, opium, one siclus of each, all powdered, and mixed with three ounces of sweet wine, which has been warmed in the sun until it has become strong. Pills are formed from this, of the size of an Egyptian bean. The dose is one pill in three ounces of wine.

According to the writer, who has selected statements from the ancient and modern doctors, these combined methods of treating all kinds of emergencies are the easiest, the safest, the most useful, and the most tried; anyone can prepare them, according to his desires.

CHAPTER 5. SPECIAL REMEDIES FOR THOSE WHO HAVE BEEN STUNG BY A SPECIFIED INSECT

Scorpion.—One starts with the general directions as mentioned, of incision, sucking, and constriction, then the application of a plaster to the wound; after this the specific remedies against scorpions are taken, according to what one has on hand.

Drink three drams of the leaves of the herba citrina, then apply the same to the site of the bite. Cantharides roots make an exceptional remedy for the scorpion bite. The maximum amount used is two drams; a plaster is prepared of it for the wound (if it is damp, it is bruised and applied directly to the wound). Boil an ounce of it in two litres of water until the strength has disappeared; then wash the wound, and apply a plaster made with sulphur and parsley, of each one part, garlic, two parts, all kneaded together. Another plaster is made of salt and linseed, of each one part, garlic two parts. A theriac which is appropriate is the one that consists of four ingredients; the dose is one to four drams.

Galen mentions a theriac specific against the bite of the scorpion and the sting of the spider: Aristolochia, four sicla, pepper, two sicla, opium one siclus, kneaded with honey, and rolled into pills of the size of an Egyptian bean. The dose is two beans with three ounces of sour wine.

All the remedies that have been mentioned against the bite of the scorpion, be they simple or combined, must be taken with pure, strong wine: for that causes a cold poison, and kills through its coldness. In absence of wine, boil up anise, as mentioned. If it is not clear, when boiled, powder one siclus of it and sift with a litre of wine. Recent physicians have found this worthy: green ischnan, powdered and sifted in a very fine sieve, softened with cow's butter, and kneaded with honey; two sicla of this will promptly quiet the pain of the scorpion's bite. Honein observes that if a plaster of white naphtha is put on the wound, the pain is promptly relieved.

The author is of the opinion that the poisonous animal which is mentioned in medical writings under the name of the runner, is a sort of small scorpion, which raises its tail, but not its head, like a scorpion, and runs fast along the ground, and hence the name. It is found in regions in the East, and it is asserted that it is more harmful than the scorpion; all the remedies that suffice for the latter, are likewise satisfactory for the former.

Spiders.—This name designates many kinds of insects, according to some, six, to others, eight; they all belong to the species of spinners, in the vernacular, spiders. The worst specimens, according to physicians, are met with in Egypt. Two species, in most countries, are found in houses; one of these is the spider with long legs and small body, which weaves its web between the wall and the garden, a fine black web; the other is of large body and short legs, and spins a white sapphire-like web in the garden, resembling the thin substance called bukran.

The harmfulness of these two species is not great, oftentimes one does not experience their bite at all; often one is bitten in the night, without noticing it; but in the morning one finds the place swollen and red. If one puts bread thereon which has been chewed in the mouth, or flour cooked in oil and salt, the swelling will soften the same day.

The other species of spider is found in ruins; some have tails; these are called tarantula in Egypt. The bite of this species is more serious than that of the scorpion, and all that helps for the latter, helps for the former. I have discovered a remedy which is specific for the bite of the tarantula, consisting of the roots of asparagus, five drams boiled with six ounces of wine, and taken as a drink. One can also place a plaster of the leaves of the herba citrina, one to four drams in wine on the wound. Drink two to six drams of the fruit of the tamarisk. Or drink ten drams of powdered mulberry leaves extracted in water. All these are to be taken in wine or in a decoction of anise; another preparation is nigella, one siclus, powdered, and mixed with cold water. Plasters can also be made of the extract of myrrh in wine; or milk of garden papaver; all used after the incision and sucking.

Bees and wasps.—Drink a solution of the seeds of althea, five drams boiled in one half litre water and one ounce wine. Or balsam leaves, one siclus in two ounces of oxymel. Also, dry casbor, and sugar, one siclus of each in cold water. Or cold vegetables, like horseradish, lentils, purslane, and gherkin; all these are curative; as is a drink prepared of unripe grapes in water. The following is a suitable plaster for the bitten area: vinegar, and duckweed, some cloth soaked in vinegar, camphor, and rose water. Or this: plaster of mallow, fresh casbor or senpriviva, or leaves of sandarac or honey and vinegar with salt.

Snakes.—It is asserted that there is nothing better than the great theriac for all deadly poisons and the bites of all animals, not to mention the bite of the adder, against the extreme harmfulness of which all the philosophers and physicians have directed their special attention, and as a consequence of many years of experience have selected the large theriac. If this is not obtainable, one can use the mithriadic electuary, and in absence of this, the trochiscus pani kaono (panacea?). Preparation: hendacochum, trifolium, round aristolochia, ruta, agrestis, pollen of iris, in equal parts, kneaded in oil. Of the trochisci prepared in this manner take one siclus in an ounce of old wine. It is claimed that this substitutes for the large theriac in adder bites, hence it should be kept ready, on hand.

Herba des fontes, that is, casbarar el-bir, boiled in wine is good for adder bites; also the root of the white vine, six drams boiled in wine. Mushroom is a good theriac against adder bite; take one siclus of it, and sift it in one half litre of old wine.

To aid in the constriction of the wound after the incision and the sucking, make a plaster of extract of brassica mixed with wine. Galen mentions a plaster for snake bite, with these directions in his own words: Serapinum, asafoetida, opopanax, one siclus of each, galbanum and sulphur, which should not be brought near a flame, two sicla of each, the dry ingredients powdered and sifted, the syrup dissolved in wine, and the whole made into the form of a plaster; put it on the wound, and cover it with a fig or nettle leaf.

Mad dog.—The physicians mention many signs of a mad dog, all of which are diagnostic; I need not go into the details in this discussion, for it is instinctive for a man to remove himself from the immediate vicinity of a mad dog when he sees one,

just as it is from an adder or scorpion, the dog himself flying before him, and crawling alone along crooked alleys, close to the walls, without barking. It is true that people take great pains to kill him just as soon as he is recognized. But sometimes it happens that the dog bites before he is identified, or that a person is bit in the dark unknowing whether the dog is mad or not. All that is to be done to cure the bite, however, should be done before the fear of water in the dog develops; after that no one, according to my experience, is able to survive. He who is bitten by a mad dog will not always suffer severe pain right after the bite, as in the case of other bites, but the disastrous symptoms which reveal the madness first appear after eight days, or often, after a long period of time. Therefore everyone who is bitten by a mad dog, or a dog of unknown disposition, must heed the general rules which have been already mentioned, namely, constriction, incision, suction, congestion through cupping, vomiting, partaking of the theriac, and the special rules mentioned in this section. These are good remedies: licum, one half of a siclus daily in cold water, nigella rubbed and sifted, one siclus daily in cold water, gentian similarly. River crawfish is by far the best; it is burned, powdered, and sifted, and one dram of the ash is taken daily in water. Of the combined remedies which Galen and others have proven, the following theriac is valuable: Myrrh, one dram, gentian, five drams, ash of river crawfish, six drams, all powdered, and two drams of the powder taken in cold water on the first day, increasing one half dram every day until on the ninth day six drams are taken; then increase no more. Another composition that has been proven is: gentian, and myrrh, each one dram, ash of river crawfish, two drams, powdered and taken daily in cold water. The following is a generally used plaster: pollen of iris, boiled in wine. Another plaster: bitter almonds, pounded with honey until quite thick. Another: leaves of damp mint pounded with salt, with asafoetida softened in wine; fill the wound with this, after enlarging it. Another: meat of nuts, salt, and onions in equal parts, thickened with honey, until it takes the form of a plaster, and applied to the wound.

These remedies should be used immediately.

The treatment of wounds by means of medicines and plasters takes at least forty days; under all circumstances leave the wound open for this length of time; if it tends to close, spread it open by means of combined plasters. As is well known, no more is to be expected than that within these forty days certain complications will arise according to the special temperament and disposition of the individual, so that in addition, purges, enemas, changes in diet, and poultices will be necessary, which, however, is not to the purpose of this discourse; that which has already been mentioned should be done from the very start, until a doctor is obtained, or if that is difficult, it will suffice to get some one who understands the situation in this peculiar state of affairs.

It is sufficient for the bite of a human being, or a domestic dog, or other poisonous animals to massage the part repeatedly with oil, until the pain has gone; then put upon the wound a half cooked bean which has been chewed in the mouth until it has become a plaster; a chewed wheat kernel is also satisfactory. If the one who chews the bean or corn is hungry, and chews it in the morning, and is a boy or a youth, the value will be all the greater. Further: make a poultice of pounded onions mixed with honey. Another remedy: pollen of iris kneaded and mixed with honey. Or: apply a small globule of sour bread which has been chewed.

This is important: the worst of all bites is that of a fasting person. If the biter has a bad mixture of juices in his body, or if he is poorly nourished, then the bite is as bad as that of a poisonous animal, and especially if the one who is bitten has recently eaten heartily, since this induces towards putrefaction, and increases the danger. The above treatment suffices in the case of the frequently occurring bites and stings which are met with in this locality. Be careful, however, to distinguish between the bite of a mad dog, and one that is not mad; for on that account many people have died, as sages have related, and as I can personally vouch. You must first be convinced, therefore, that the biting dog is not mad, and then you can proceed in the manner explained, and close the wound. If there is any doubt as to the dog being mad, presume that he is. An old well informed doctor told me that he saw a spinning factory boy who was bit by a dog; the animal by chance did not appear right off to be mad; and the doctors did not so pronounce the dog; so that the wound was allowed to close after a month or so. The boy improved, and for a long time conducted himself in a normal fashion, when finally he became apprehensive of death and died. Beware therefore of conducting yourself as above, for there is no analogy to the virulence of this poison.

CHAPTER 6. DIET IN GENERAL AND PARTICULAR FOR THE BITTEN PERSON, TOGETHER WITH A FEW APPROPRIATE SPECIFICS

All persons who have been bitten or have taken poison should eat bread with oil and butter, fresh milk, meat of figs, pistachio and other nuts, avellana, garlic, onions, and ruta; these can be eaten singly or together; avoid meat and especially fowl, for meat tends to cause the blood to putrefy, on account of the particular nature of the poison. Eat plenty of salt at meals, for that tends to dry up the poison; honey is beneficial; and there is nothing better than butter. I know of no sufficient foundation, neither rational nor traditional, for the spread of the idea among certain communities, that the bitten one should eat only unleavened bread. He should drink as much wine as he can, and mix it with his food, particularly if he was bitten by a scorpion, in which case highly intoxicating wine is indicated. Also take large quantities of nuts, figs, garlic, and ruta in strong wine, for the alleviation of the pain. Thus far the treatment outlined is for one who is chilly or slightly warm. If the bitten person is feverish, and calls for much water, then he can take sour things with a little butter; he should suck a sour apple or sour pomegranate, and drink pomegranate juice. If the inflammation is severe, let him eat cold vegetables, like endives, lenzones, lettuce, and cucumbers; it is imperative that they should be taken with oxymel; the drinking water should be mixed with some wine; do not omit to eat the meat of nuts and figs; and above all eat cautiously according to the strength of the fever.

(To be continued)

Editorial Articles

CLIMATE AND CIVILIZATION

A great deal has been written at one time and another on the effects of climate on man, on character, energy, hardihood, mentality, and so on. Of course it is obvious that climate has an immense influence on man and his doings. The book entitled *Climate and Civilization,* by Elsworth Huntington, of Yale University, sets out to show how climate has influenced the destiny of man. A bracing, stimulating climate produces a race characterized by energy of mind and body and by initiative and perseverance, and consequently should produce the highest standard of civilization. This is borne out by facts to a certain extent. The civilization of northwestern Europe, where the climate is cloudy and invigorating, is of a high grade and conducive to the raising and development of a vigorous race. Great Britain, Germany, Belgium and Northern France are populated by energetic races fashioned and moulded by climate. At the back of all lies the question of health and this is determined by climate to a very considerable extent. The prosperity of a nation depends on the physical and mental fibre of the inhabitants. This hinges on the air, food and water which falls to their lot, and which in turn is chiefly a matter of climate.

But while climate has most to do with the making and development of a nation it cannot save a population from the evils of civilization. A departure from the more primitive modes of living and the introduction of enervating and luxurious habits generally spells the fall of a nation, however stimulating its climate may be.

Mr. Huntington points out that the human animal now rides instead of walks; lives in stuffy houses instead of out of doors or in caves; wears clothes instead of exposing his body to the weather; and eats soft concentrated food instead of that which is raw, tough and bulky. He preserves the sick and weakly instead of letting them die; he permits an economic and social system which causes the people with greatest mental power to have the fewest children, while the stupid breed like rabbits, and so on.

The evils of civilization if allowed to continue unchecked will wreck a nation reared and brought up in the most invigorating climate, but this is in spite of the climate. It may be taken as an axiom that climate has a remarkable influence on character, that a people bred and raised in an enervating climate will be listless and apathetic and that a population born and brought up in a bracing climate will be energetic.

Too great prosperity is one of the chief evils of civilization, against which precautions must be taken, and it seems as if in his book Mr. Huntington is warning the people of this country to beware of this evil.

POSTURE

Posture is one of those subjects about which the more one knows the less he knows, and of which those who have studied least speak with most assurance.

Posture is the resultant of complex anatomical and physiological conditions, but the conditions usually considered as producing it are the simple ones of wrong habits of sitting or standing.

We talk glibly about good posture and bad posture. Anyone will classify a hundred persons into those having good posture and those having bad posture, but no two persons would agree in their classifications and they will find difficulty in placing a considerable number in either group. When he has finished, not even the classifier will be able to say that those whom he believes to have the best posture are any better off for having that posture, so far as health goes, than those who may be possessed of "bad" posture, nor can it be said that many of those with "poor" posture can by any means be brought permanently into the group designated as having "good" posture. Only those who have worked longest at trying to improve posture know how little can be done along these lines of endeavor.

Dr. E. H. Arnold, of the Arnold College of Hygiene and Physical Education, has been delving into the foundations of "good" and "bad" postures. He has, in other words, been studying the structure of individual vertebral columns and of the pelves from which these columns arise. Anyone who has seen much of bones from many skeletons is impressed with their great variation in size and shape and (so far as the spine is concerned) in number. Arnold has made his study of students of beyond high school age in the living subject by x ray pictures. He finds, of course, this same variety of shape and size and number of vertebræ and the postures of the pupils depend, to a very large degree, on these structural foundations and on structural faults. One can apply exercises or even orthopedic appliances to these persons for years without effect, for they cannot reshape the foundation stones.

Some persons classified as having poor posture are so from heredity, some fall into this class from

other developmental agencies, while postnatal nutritional causes account for many of these boney variations which are really normal or good posture (at least, the best they will ever have) for the persons possessing them. In the years beyond youth, occupations or arthritic diseases account for not a few cases. The result of our treatment of these structural cases is usually slight, as is to be expected.

Besides the large number in which a posture which we call poor is due to structural conditions, there are many cases due to neuromuscular weakness, back of which are chronic disease, poor nutrition or fatigue. A change to what we assume to be good posture can undoubtedly be brought about in many or most of these cases by getting at the real causes, though not merely by exercises or by telling the person to straighten up. Round shoulders, however, can, in the great majority of cases, be cured.

After all is said, or done, we still do not yet know where to draw the line between good posture and bad posture so far as the effects of posture on the individual are concerned. What we pronounce bad posture for one person is, in most cases, doubtless as good for that person as the posture called good assumed by another person. We are too often applying purely esthetic standards where they do not belong. Even our esthetic standards along these lines are incorrect if we may trust the art of the Greeks, for their good posture is one of ease and comfort—of naturalness rather than such very commanding having-your-picture-taken attitudes shown in portraits of George Washington or of Queen Louise which are usually held up as models for lesser mortals. We wonder whether these persons always carried themselves so or whether it was only for pictorial purposes. At any rate, if they did so their backs were built differently than those of most of us.

MEAT EATING AND HEALTH

Of all the speeches made at the recent gathering of the American and Canadian medical profession in London, that of Dr. Wood Hutchison attracted the most attention. The reason for this was that he spoke on a subject which the man in the street can understand and one which has been widely discussed by medical men both in medical and lay press during the past few years. Also Dr. Wood Hutchison expressed views which are not held or taught by the majority of the medical profession, but which are perhaps in consonance with the tastes of most laymen.

There has been to some extent a campaign almost against meat eating by a section of the profession. Possibly, in their zeal for dietetic reform, they stigmatized the consumption of meat more forcibly than was warranted by evidence. Also they may have lauded a vegetarian diet more highly than appears to have been proved by the test of experience. On the other hand, it seems that Dr. Wood Hutchison in his anxiety to show that the new teaching on diet is wrong, or rather does not agree with his views, went further than scientific evidence or even common sense facts go, in his eulogy of meats or of any diet which most strongly appeals to the palate of a patient. In the first instance it may be said that a certain amount of exaggeration has been employed by those who urge that little or no meat is required to maintain an individual in health. In considering this question many points must be weighed carefully. The occupation of a person, the conditions under which he or she works, age, the climate, personal idiosyncrasies and so on. The young strong man or a man in the prime of life engaged in hard manual labor in the open air, in a cold or temperate climate, can assimilate, and thrive on a quantity of animal food which would be harmful to a man who was doing light work or leading a sedentary life. In the case of the manual laborer in the open air in a cold or temperate climate who will say that meat is not the most suitable food for him?

Although it may be urged that the Italian does work equally hard in the open air on a diet almost vegetarian, the protein he ingests being, as a rule, mostly in the form of cheese. But in the case of the Italian the work is done for the most part, in a warm or comparatively warm climate. Age again is a factor to be considered. After a certain age, the bodily powers fail, and the consumption of a considerable amount of meat may place too great strain on the kidneys and the digestive organs. Moreover, the personal equation must always be taken into account. "What's one man's meat is another man's poison." Habit is another factor which plays a part. If a child is brought up on meat, as New Zealand, Australian and Canadian, most American and British children are brought up when their parents can afford it they seem to do well on it. So do also the Italian children on a vegetable and cereal diet with a certain amount of non-animal protein and they appear to reach a green old age on a fair average of life, on such a diet. It is likely that the meat eating races as New Zealand, Australia and Canada, cited as examples of the beneficial results of meat eating, do not have the lowest death rate in the world merely because they are large meat eaters, but partly because they live for the most part a healthy out of door life in a good climate and are not stinted for food.

In the cities sanitation and hygiene is good and assists in keeping down the death rate. Of course, there is much variance of views on the diet question

but as far as civilized life is concerned a few facts seem to thrust themselves forward. One is that, as a rule, the well to do eat more than is good for them and above all eat food which has been overcooked. The poor do not get enough to eat; what they do get is frequently unsuitable, generally of inferior quality and almost always overcooked or badly cooked and lacking in essential qualities.

The great fault of civilized diet is that it is too often overcooked and before being cooked has been robbed of its most nutritive properties. It is allowed on all hands now that a food to be up to the proper standard should contain a more or less definite proportion of the mineral salts and of the vitamine elements. What then does it profit a man if he is given food which even before being cooked has been robbed of some of its valuable properties and is then so cooked that it is robbed of other almost essential properties. It is too sophisticated food and the overcooking of food that are among the greatest drawbacks of civilization.

This applies to meat, which is cooked frequently so that little virtue is left in it. Dr. Wood Hutchison is by no means alone in holding that the campaign against meat eating is being carried to absurd lengths. Dr. Harry Campbell has long contended that man is naturally a carnivorous animal and that on protein in the shape of meat he does his best physical and mental work. But Dr. Campbell advises discretion in the consumption of meat and does not recommend it in large quantities for the sedentary or the elderly or aged. He, however, does insist vehemently that the tendency of the age to eat pappy food from which most of the nutritive properties have been extracted and which give no exercise to the jaws, to the salivary glands or to the functions of digestion, is most harmful and responsible for some of the diseases, and for a great deal of the ill health which prevails. Another forcible and pungent writer on dietetics, Dr. Leonard Williams, while he is not at one with Dr. Campbell on the question of meat, is most insistent on the point that food nowadays is overcooked far too much and uncooked vegetables and fruit, which contain all their natural elements including the vitamines placed in them by the sun, should form the greater part of a person's diet.

Dr. Wood Hutchison's refreshingly frank speech has done good in that it has once again thrown the limelight on a subject which is of the first interest and importance to the community and which is still open to argument. Further, it is to the medical man that the public look for enlightenment. Already great progress has been made in the science of dietetics, and the disputed points are gradually being elucidated.

WHAT IS HEALTH?

Educators are quite generally agreed these days that health should be given most importance in the school curriculum. At the same time some of them point out that health is something we cannot define. In a way health cannot be defined, but neither can we define life and we are constantly revising our notions about such fundamental phenomena as matter and energy. Even when we work out our definition of health it does not apply specifically as does a definition of electricity or of ether, for the health of one person is by no means the health of another.

Such a knowledge of the elusiveness of health and its dependence on heredity is of the greatest importance to health workers in order that they may be prepared to meet the demands of the occasional layman who demands proof of the results of efforts in sanitation and hygiene. It is perfectly easy to show that the substitution of a clean water supply for one infected by typhoid bacilli is a valuable procedure. Death rates and case rates give mathematical proof. But when it comes to evidence that medical inspection of school children or the teaching of hygiene to such children are producing results in better health we have practically nothing but *a priori* arguments to go upon. We do not know what would have happened had these children had no medical treatment and no information in hygiene, though we can surmise, from a few outstanding examples, of the effects of treatment that they would all have been worse off.

To the layman the weighing and measuring of results seems exceedingly simple, for we invariably believe more in the magic of an art with which we are unfamiliar than in the one we have studied most.

We cannot measure our own health from day to day, save to distinguish it as better or worse and even here the condition of our health may be one of mental origin, a mere state of mind, which will disappear over night. One human organism whose health we call delicate may be of more service and over a longer period than another whose health we pronounce robust. In other words, robust health is often less important than delicate health in that the former may exist in an organism which is destined by heredity and habit to go to pieces at a much earlier date.

If it is difficult to know when one is in health it is as difficult to say when he is just out of health, especially in a life that is filled with complex mental and physical conditions. The best we can do is to find out our bodily weaknesses, hereditary and acquired, and, as Lord Bacon said, take counsel of each daily experience. The physician can only seek out organic weaknesses and advise as to the limitations set by heredity, by acquired defects, and occupation.

Obituary.

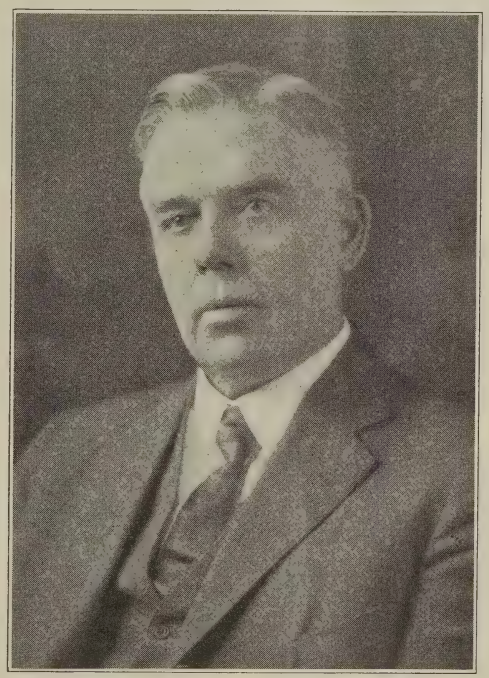
CHARLES B. DUNLAP, M.D.

Scarsdale, New York

Dr. Charles B. Dunlap has passed away. His sudden death on Sunday, June 6th, came as a great shock to all his friends and associates. Although Dr. Dunlap had not been well for some time, his condition was not considered serious; and he was active until the last. He attended to his professional duties on Saturday, and died at his home, in Scarsdale, the following day.

Dr. Dunlap was chief associate in neuropathology at the Psychiatric Institute on Ward's Island for twenty-four years, and was professor of neuropathology at the University and Bellevue Medical College.

Dr. Dunlap was born in Cambridge, Massachusetts, in 1863, and spent his youth in Monroe County, West Virginia, which had been the home of his family for many years. He returned to Cambridge to enter the Cambridge Latin School, and then entered Harvard College and was graduated in 1889. In 1893 he was graduated from the Harvard Medical School.



CHARLES B. DUNLAP, M.D.

After an internship in the Boston City Hospital, Dr. Dunlap served in the McLean Hospital for the Insane in Waverly, Massachusetts, and in the Massachusetts State Hospital for the Insane in Worcester, Massachusetts. He came to Ward's Island in 1902.

In September, 1902, Dr. Dunlap married Miss Anna Weld Carret, of Cambridge, who survives him, with three children, Martha Weld, Ruth Weld and Charles Edward Dunlap.

Dr. Dunlap is no more. He was laid to rest in Greenville, West Virginia, the home of his boyhood. The medical profession has lost a well balanced mind, slow to form or to accept an opinion, slow to judge or to criticize, careful in his deductions and conclusions. It has lost a man whose unfailing interest in his work was never overshadowed by any material interest. This was a fundamental characteristic of his nature. He valued money only because it was necessary to sustain life. He never gave it a higher place, and would not sacrifice one principle in its favor. He worked for the joy he found in his work, for the good his work might do. He was a true scientist. Those who knew Dr. Dunlap personally, knew him to be a devoted husband and father, always thoughtful, gentle, kind, sympathetic and generous. "Ye canna expect to be baith Grand and Comfortable," an inscription over the hearthstone of his late home, expressed the magnanimity of his being. He loved simplicity, and his home life was a reflection of this quality. He was a staunch friend, and those who shared his friendship will always revere his memory and gain inspiration from it. Dr. Dunlap is dead. The world has lost a noble soul, but the world is better because Dr. Dunlap has lived.

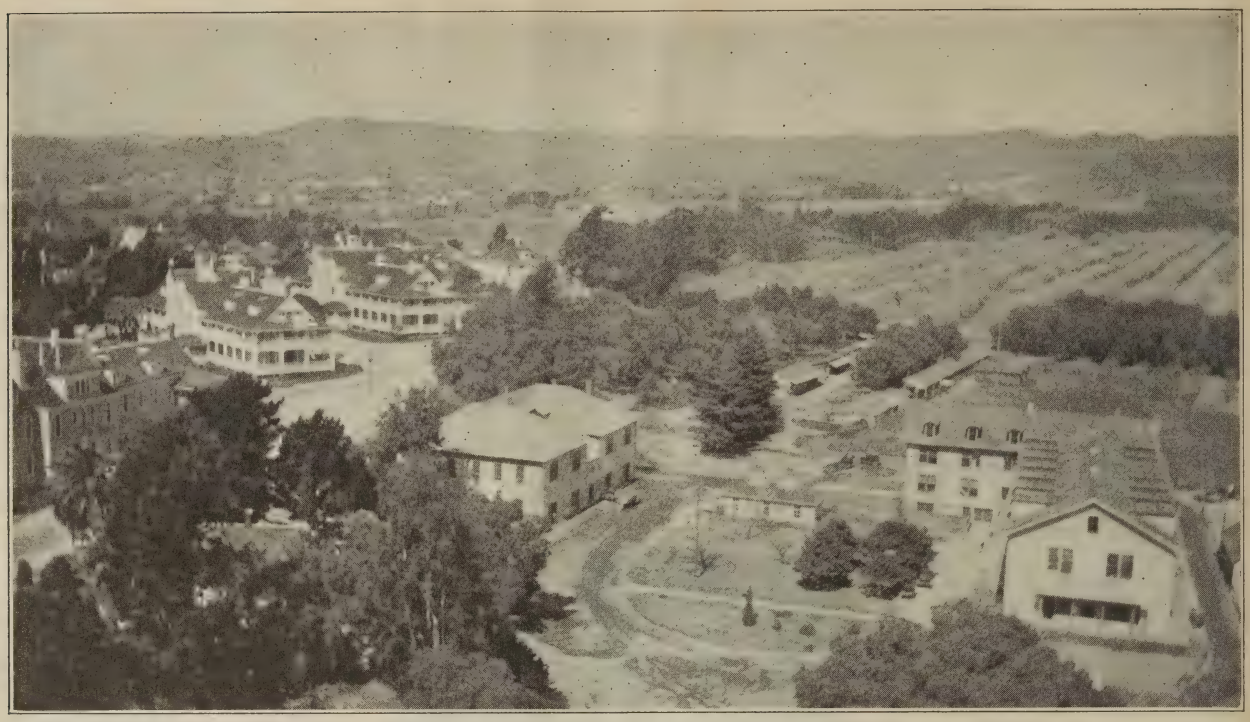
SIR JOHN WILLIAMS, BART, G.C.V.O., M.D. F.R.C.P.

London

Sir John Williams, a well known gynecologist and obstetrician of a former generation, died on May 24, 1926, at Aberystwyth, Wales. Although, perhaps, almost forgotten by the present generation, the name of John Williams in the heyday of his fame was one which carried great weight in medicine and surgery.

He was born in November, 1840, of yeoman stock, his father being both a farmer in Carmarthenshire, Wales, and an ordained minister of the Congregational Church. When a boy John went to the village school, then to the Normal College at Swansea, and in 1861 to University College, London. He qualified as licentiate of the Society of Apothecaries in 1865 and held several hospital appointments. When he had taken the M.B. degree in London he returned to Swansea and settled down as a general practitioner. In 1873 he was appointed assistant obstetrical physician at University College Hospital, London. In 1883 he became obstetrical physician jointly with Dr. Graily Hewitt, and in 1887 professor of obstetrical medicine at University College. He was then appointed to the Court of Queen Victoria, and for some time was in England the undoubted head of his branch of medicine. Honors followed. He was made a K.C.V.O. by King Edward and a G.C.V.O. by King George. The King of Denmark gave him the Grand Cross of the Order of the Dannebrog; the Universities of Edinburgh, Aberdeen and Glasgow made him LL.D.; he became D.Sc. of the University of Wales, Fellow of the University College and Honorary Fellow of the Royal Society of Medicine. In 1903 he retired to a country house in Carmarthenshire and devoted his time and energy to setting up the Welsh National Library.

Mathews Duncan revolutionized the teaching and practice of gynecology and obstetrics in London and John Williams was his chief helper. He was a skilful but conservative operator. He became president of the Obstetrical Society in 1887 and in the transactions of the society there will be found most of the many papers that he wrote. The last years of his life were given up to the work of establishing a national Welsh library which is in the process of becoming one of the great libraries of the world.



Convalescent Barracks

National Soldiers Home Hospital*

LEONARD E. CROFT, M.D.
and DONALD G. BUSSEY, M.D.
Los Angeles.

This hospital, which is a part of the Pacific Branch of the National Home for Disabled Volunteer Soldiers, is located on a beautiful 860 acre tract in the foothills of West Los Angeles. It was established in 1888, by act of Congress approved March 2, 1887; the sixth of the ten branches now in operation. Those entitled to its benefits include, "All honorably discharged officers, soldiers, and sailors who served in the regular or volunteer forces of the United States in any war in which the country has been engaged . . . who are disabled by disease, wounds or otherwise. Also those who have been honorably discharged from the Army, Navy or Marine Corps of the U. S., necessitating treatment of service origin or not." Obviously there will be a large group of men who are disabled to an extent entitling them to admission, but not necessarily requiring care in the hospital.

We have some four thousand odd of this class at the Pacific Branch, and they comprise the personnel of the convalescent barracks or companies where lodging, meals, clothing, medical service, and various forms of entertainment constitute a share of what the "muzzle-loader," "bamboo," our "hero" may have "coming to him." We have twelve such companies here, three of which have daily visits by nurses and doctors, so that more gradual transition from hospital to activity is made possible. In addition a dispensary or "sick-call" is maintained every morning, and a doctor and an ambulance are subject to call anywhere in the camp, day and night.

*Under the direction of Col. James A. Mattison, F.A.C.S.

CAPACITY

The hospital has a capacity of over eight hundred beds including a new tuberculosis annex of three hundred beds. Fortunately a new eight hundred bed hospital is under construction at the present time, and the much needed space and improved facilities will be at hand within a few months. However, more about the new hospital a little later.

Our institution has been called, "An Old Soldiers Home"; we resent the appellation and deny the implication. Our hospital and convalescent barracks are not static but progressive, up-to-date and efficient, the purpose being to rehabilitate the chronic as well as the acutely ill. We are well equipped with the approved facilities essential to the practice of modern scientific medicine, staffed by medical officers of experience, and aided by consultants of recognized attainment.

An admitting office is maintained where examinations are made for the purpose of determining whether a patient is primarily a convalescent company case or one for immediate hospitalization. If he is in the latter class the patient is sent to the admitting ward where the physical findings are checked, and the routine examinations are ordered. These include Eye, Ear, Nose and Throat, Dental and

Laboratory surveys, as well as any necessary röntgenological work. The case is then referred to the indicated special department for final diagnosis and treatment.

The following departments are maintained: General medical, surgical, genitourinary, orthopedic, neuropsychiatric, eye, ear, nose and throat, and tuberculosis. With these should be included the x ray, laboratory and dental departments. When a case is referred from one department to another the findings are checked by the Assistant Surgeon[1] in charge and are then surveyed by the visiting consultant.

SURGICAL DIVISION

The Surgical department is under the direct supervision of the chief medical officer, Colonel James A. Mattison. A surprisingly low mortality rate obtains in view of the usual type of case met with in this service.

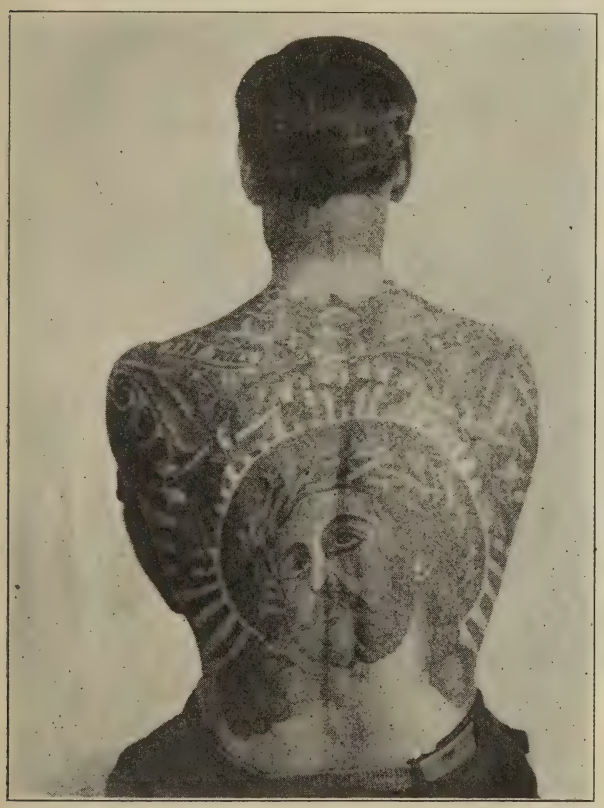


FIG. 1.—A tatooed man. A veteran of the Spanish-American War; tattooing was in style during World War.

The Medical department with the aid of our medical consultant, Major John William Shuman, F.A.C.P., has rendered a valuable service in the diagnosis and treatment of many obscure cases that have drifted from one hospital to another, the subjects of indefinite diagnosis and ineffective treatment. Practically all surgical cases are surveyed by the Medical department prior to operation. Every three months the Medical Staff hold a clinic for the Santa Monica Branch of the Los Angeles County Medical Society and visitors. Material for the same is not lacking. The accompanying photos give but a faint idea of pathological conditions which come to us. These, however, offered no difficulties in diagnosis. However, the lymphosarcoma man had previously been diagnosed, Hodgkin's disease. He died and was autopsied. All reasonable effort is made to examine after death and checkup the clinical diagnoses the

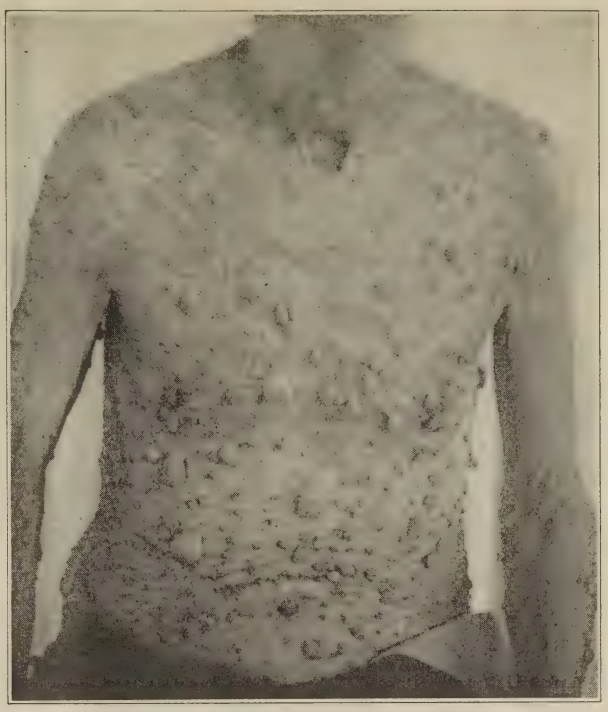

FIG. 2.—Civil War veteran. Multiple neurofibromata. Age eighty-two.

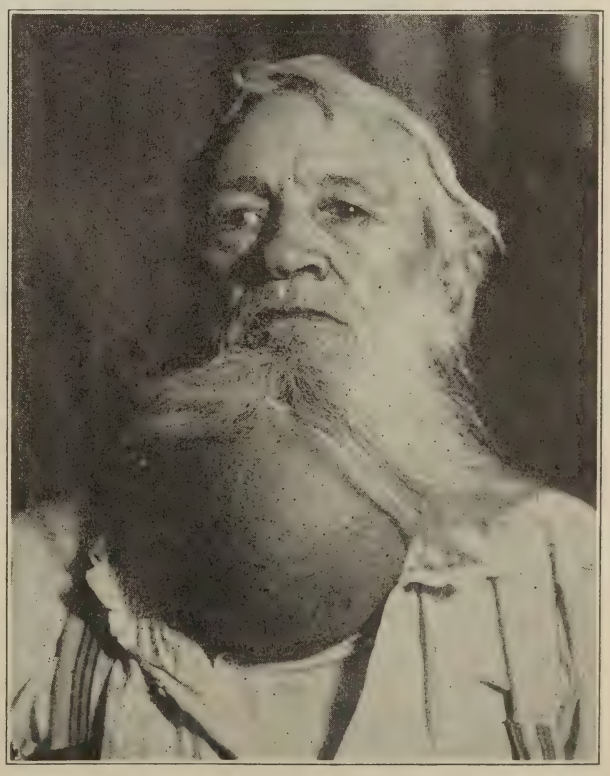

FIG. 3.—Civil War veteran. Cystic goitre.

[1]Assistant Surgeon, a title for all medical officers, excepting the surgeon in charge.

same as in any well organized up to date hospital, for the good of the Service.

The orthopedic department is proving to be one of the most valuable and popular departments in the general hospital service. As might be expected a large percentage of the disabled ex-service men suffer from disabilities of an orthopedic nature. As a result the orthopedic clinic under the supervision of Captain Charles Stephen James, F.A.C.S., is even at this late date still placing men disabled in the late war both figuratively and literally on their feet.

In an institution of this kind the genitourinary department plays an important part. Someone has said that our government hospitals are filled with syphilitics who have been badly treated. We have our share of advanced cases of syphilis, but we insist on accurate, careful, and adequate treatment. A blood Wassermann is a routine on all admissions. We do a considerable quantity of prostatic, kidney, and bladder surgery, with the assistance of consultant Dr. Leon J. Roth, and have adequate facilities to care for any type of genitourinary case by modern methods.

The scientific handling of the participants in the recent and other wars who require treatment for nervous and mental disabilities has been a problem. While we accommodate a limited number of such cases our facilities are entirely inadequate to take care of the demand. The neuropsychiatric department is merely a part of the general hospital and these patients are treated the same as all other sick people. Thus we avoid the stigmata of an asylum. Other advantages are the large convalescent barracks, and the fact that commitment is not necessary in order to treat our mentally ill cases. We are fortunate in having Dr. Paul Bowers as our consultant in this department.

Fig. 4.—Convalescent barracks No. 11.

The eye, ear, nose and throat department in addition to routine examinations on all admissions takes care of treatments and operations including refractions. Two clinics a week are held, one in opthalmology under the supervision of consultant Dr. F. A. Edwards, and one in otolaryngology under the supervision of consultant Dr. H. P. Merrill. Cases for operation are previously surveyed by the consultants.

The X Ray department, under the direction of Dr. R. C. Shawhan is most modern. The average number of films per month being between six and seven hundred. In this as in all other departments of this hospital wonderful opportunities are had to follow up our cases, diagnostically and therapeutically.

One of the important activities in our hospital is occupational therapy. It has been proven in many places that the period of hospitalization of many patients may be considerably shortened by the intelligent use of this splendid form of treatment. Naturally the relationship of the type of work to the patient must be carefully considered and selected, and this is done only by the ward surgeon in charge of the case. The work may be done either in the shops or at the bedside, and competent aides are at hand at all times.

The Physiotherapy department is large, and well equipped with all the modern proved equipment for carrying out this form of treatment to best advantage. It is under the direct supervision of one of the assistant surgeons, and assisting him are a number of well trained graduate physiotherapy aides.

In connection with the convalescent cases outside the hospital, a feature worth noting is the quarterly inventory of the health of all patients. Every three months those who have been in the institution for a period longer than that time are called before an examining board and given a careful examination in an effort to determine what can be done to speed up their convalescence. Cure rather than care is our aim.

In regard to the new million and half dollar hospital for general, medical and surgical cases: It is to be seven stories high, fireproof and modern throughout, including the "last word" in equipment. Work on the second story is going on at this writing.[1] A roof garden will afford ample opportunity for heliotherapy. The grounds adjacent to this new building are being surveyed for a nine hole golf course.

Society News and Notes.

The Wisconsin Antituberculosis Association is issuing a series of interesting little pamphlets on Great Physicians as Benefactors of Mankind. The purpose of the leaflets is to supply to high school teachers authoritative historical and scientific data which is usually unavailable outside the medical libraries.

The will of the late Gustav Ulbricht provides $2,000 for the Pasavant Memorial Homes; $50,000 for the New York Association for Improving the Condition of the Poor, and $25,000 to the Cornell University.

* * *

The Sharon Sanatorium, Sharon, Massachusetts, and the Central New England Sanatorium and Tumor Colony, Rutland, Massachusetts, received $150,000 by the will of the late Mrs. Thomas O. Richardson.

* * *

One thousand dollars was bequeathed to St. Joseph's Home for the Blind, Jersey City, by the late Nellie Lynn, of Philadelphia.

* * *

The New York Skin and Cancer Hospital received $300,000 as a contingent bequest from the estate of the late Ralph Holden.

* * *

The Memorial Home for the Blind, Worcester, and the Perkins Institution for the Blind, Watertown, Massachusetts, each received $5,000; the Home for Aged Women, the Home for Aged Men, Associated Charities, Worcester Tuberculosis Relief Association, and the Worcester Soviety for District Nursing, each received $2,000 by the wil. of the late David Hale Fanning, of Worcester.

* * *

One thousand dollars was bequeathed to the Brooklyn Home for Consumptives by the late Grace Newman.

* * *

The will of the late Mrs. Mary de Silver Lord provides $2,500 for St. John Guild's Seaside Hospital, New York, and $10,000 for St. Bartholomew's Hospital, New York.

* * *

By the will of John McCaffery the Hospital of St. Elizabeth of Hungary, New York, received six thousand dollars; the New York Society for the Relief of the Ruptured and Crippled, the Servants for the Relief of Incurable Cancer, St. Vincent's Hospital, New York Ophthalmic Hospital, Manhattan Eye, Ear and Throat Hospital, New York Cancer Hospital, Metropolitan Throat Hospital, French Hospital, St. Joseph's Hospital, each received seventy-five hundred dollars.

* * *

The late Mary E. Russell provided thirty thousand dollars for The Massillon City Hospital, Massillon, Ohio, in her will.

* * *

The Babies Hospital, of New York, and Columbia University each received twenty-five thousand dollars by the will of the late Dr. L. Emmett Holt.

* * *

The will of the late Miss Elizabeth D. Barclay, whose estate amounted to about two hundred thousand dollars, contained bequests to endow beds in hospitals, and bequeathed a share of the residuary estate to the Philadelphia Orthopedic Hospital for the purchase of appliances and instruments for the care or comfort of deformed or crippled children.

* * *

The New York Tuberculosis Association has for distribution a pamphlet entitled *Getting the Most Out of Your Cure.*

* * *

The Jewish Hospital, Association and Federation of Jewish Charities, Philadelphia, each received twenty-five thousand dollars, under the deed of trust created by the late Benjamin W. Fleisher.

* * *

Under the will of the late Mrs. Mary Clark, the Woman's Hospital of New York will receive three hundred thousand dollars direct; also a contingent bequest of approximately $1,270,000 from the same source.

* * *

The Coatesville Hospital, Coatesville, received five thousand dollars by the will of the late Miss Charlesanna L. Huston, Germantown, Pennsylvania.

* * *

Frederick Brown has donated one hundred thousand dollars to the Jewish Hospital of Brooklyn.

* * *

The will of the late Dr. Julius Rudisch provides, in a contingent bequest, that his estate of "more than $50,000" shall ultimately be divided between the New York Physicians Mutual Aid Association and Mount Sinai Hospital, of New York.

* * *

An anonymous donor has given $250,000 to the London Hospital to aid in paying salaries to research workers. There is to be an annual scholarship of $500 open to students from Oxford and Cambridge; a research scholarship of $2,000 a year, tenable for three years; the remaining sums to be divided between two senior pathologists. The two present holders of the last are Dr. S. P. Bedson of the Lister Institute, and Dr. W. Howard Florey of Cambridge University, engaged in this country with the Rockefeller Foundation.

* * *

The American Red Cross has recently announced that first aid and life saving instruction will be repeated at eleven different places in the United States as part of its National Water Safety Campaign. Among the instructors will be a number of well known athletes, both men and women, and various heads of physical education departments throughout the country. The New York course will be given, June 16th-26th, at Camp Matinecock, Tuxedo.

* * *

The Bureau of Clinical Information of the New York Academy of Medicine has now in press a booklet entitled *Opportunities for Clinical Study in New York Hospitals.* This constitutes a revision and expansion of the book of fixed clinics published for several years by the bureau. The new booklet will contain maps of the city and directions for reaching its hospitals. Special features and activities of interest to visiting physicians will be indicated, and opportunities in filling general and special internships, clinical clerkships, fellowships, and assistantships will be described. A list of graduate courses, clinical conference and clinics, with dates, places and time, follows.

* * *

Dr. Genil-Perrin, secretary general of the *Ligue Française d'Hygiène Mentale,* contributes an interesting article to the May number of the *World's Health* outlining the history and activities of the International Organization for Mental Hygiene. The writer makes a forceful plea for pushing mental bygiene throughout the world as a part of public health programs, addressing his remarks particularly to the League of Red Cross Societies because of their peculiar fitness to inaugurate and carry on such work, and because, through their central secretariat, they might plead the cause of mental hygiene before the League of Nations. He advocates, 1, That the Red Cross Societies include mental hygiene in their public health programs; and, 2, That the League of Red Cross Societies take part in the international organization of mental hygiene, and that it establish a new international secretariat for this purpose, if and when funds adequate for its continued and active maintenance are obtained.

* * *

The Save the Children Fund International Union has ceased publication of its *News Bulletin* and its supplement entitled *Salvate Parvulos,* and has substituted for them the publication of the *Revue Internationale de l'Enfant.* An editorial in the first number states that the chief aim of the new review will be to establish a liaison between child welfare specialists in different countries. It will publish original articles and news in English, French, German, Italian and Spanish.

* * *

The recently issued annual report for 1925 of the American Red Cross describes its work done in the alleviation during the year of 61 domestic disasters, 50 of which were what are tabulated as major calamities. Of these 18 were fires, 12 tornadoes, and 9 floods. A total of 46,098 persons received relief during the year.

Book Reviews

MATERIA MEDICA AND THERAPEUTICS

Potter's Therapeutics, Materia Medica and Pharmacy. Fourteenth Edition. Revised by R. J. E. Scott, M.D. Philadelphia: P. Blakiston's Son & Company, 1926.

It is regrettable that new edition of books on materia medica and therapeutics are so frequently not deleted of ancient useless drugs and more useless and ridiculous prescriptions. Textbooks on the subject of therapeutics are practically the only textbooks that are not kept up to date. The reviser of a book on materia medica and therapeutics, if he was the original author, seems to find it very difficult to cut out what he has said in his previous editions, so he keeps the old material and adds the new, making a book of historical therapeutics instead of using the scissors and offering a book of the best drugs and up to date advice for their use. We still bend the knee to the mystery of something that was once said to cure.

In the present instance the author of this edition is not the original author or the author of the previous editions. Hence without personal anguish he could have been lavish with his deletions. The older books can well be left for reference to old valueless drugs and treatment. Let the new books discuss modern treatment only, else the reader and student is befogged and wearied.

In his preface Dr. Scott says he has deleted "much obsolete matter and a number of the older prescriptions." He did not go far enough. The book is arranged alphabetically for reference. Part I, devoted to drugs, comprises pages 59 to 513, and the discussion of the action of drugs is excellent. The advice as to the therapeutic use of alcohol is correct. Medical men should not bend the knee to prohibition cranks. Also, there should be no laws that decide the dose of alcohol that a physician shall prescribe, any more than should there be a law declaring what dose of morphine or quinine it is allowed the physician to give. It would seem well to have more discussion of the endocrine gland extracts.

There is no attempt to follow the United States Pharmacopœia in giving the doses in the metric system. All the doses are in the old system. When will books and hospitals accept and teach the scientific decimal dosage? Most every hospital still has its "so many grains to the ounce" of nitrate of silver and "so many parts to the thousand" of corrosive sublimate.

Electricity, etc., is discussed in alphabetical order, many forms under "E." There is a fine discussion of sera and vaccines.

Part II is devoted to pharmacy and prescription writing, in which are perpetuated many old and ancient prescriptions. Who now puts nitric acid and hydrochloric acid into a bath? A prescription for this appears on page 548. There is also a prescription for a sulphur bath which includes precipitated sulphur and dilute sulphuric acid. On page 550 is a prescription for an "Electuary for Piles," and also one entitled "The Chelsea Pensioner." On page 556 are two prescriptions for gargles, one containing ammoniated tincture of guaiac, compound tincture of cinchona and honey, which, it says, should be well agitated and to which should be added potassium chlorate and water. Another contains alum, pomegranate bark, petals of red rose and honey, made up with boiling water. On page 559 is a prescription for a liniment that is not safe. It contains tincture of aconite, tincture opium, tincture arnica, chloroform, and soap liniment. One wonders if any oculist would use the following collyrium (page 560), which contains zinc sulphate, iron sulphate, copper sulphate, and alum in distilled water. One wonders how a child could be made to take the following prescription (page 564): powdered sulphate of quinine 1.5 drams; powdered acacia 1.5 drams, in syrup of ginger 4 ounces, a teaspoonful thrice daily. One would wonder just what this "paint" was at (page 565): tincture of iodine, ether, tincture aconite, fluid extract of belladonna root, morphine, iodine. Hardly believe we need Hooper's female pills, containing eight ingredients (page 570). Also one wonders why a pill (page 571) containing strychnine, arsenic, belladonna, quinine and iron is entitled "a tonic pill for women." How could it hurt a man? The prescription for catarrh powder which contains morphine is inexcusable (page 572). "Wade's bougies" (page 575) containing iodoform, bismuth, chloral, morphine, oil of rose, gelatin, and glycerin is of course ridiculous. Why insult oil of rose in an iodoform mixture?

Part III is devoted to special therapeutics also arranged alphabetically, and the previous author and the present author have seemed unwilling to delete anything; much of the advice is good. But (on page 596) who would ever administer dilute nitric acid in tincture of calumba and water for aphonia? One third of a page only (597) is devoted to the management of apoplexy, and prescriptions for tincture of aconite and croton oil are listed. Of course they might be indicated. On page 604 Bartholow's prescription for cigarettes to be dipped in an arsenic solution should be deleted.

It is hopeless to endeavor to discuss pro and con all the drugs, past or present, used in the treatment of a disease. A therapeutic book should outline or recommend the best modern treatment. As an instance of this futility of discussing everything (even quoting some old authority) note under the title of pneumonia the use of the following drugs are briefly discussed: creosote, creosotal, guaiacol, duotal, quinine, salicylac acid, aconite, veratrum viride, camphor, strychnine, digitalis, phosphorus, belladonna, tartar emetic, antipyrin, opium, ammonium carbonate, turpentine, serpentaria, potassium iodide, ammonium iodide, ethyl iodide, sodium iodide, ipecac, senega, sanguinaria, adrenalin extract, serum treatment, alcohol and oxygen. Reference is made to physical treatments, including blisters, cupping, poultices, wet packs, etc.

How can the subject of cancer be discussed in one and one fourth pages! Everyone knows that opium will stop pain, but does arsenic internally diminish cancer pain and check vomiting? Should ten grains

of chloral be given three times a day for the pain of cancer?

Is cerebral anemia (page 624) a disease? For this condition is recommended arsenic, iron, amyl nitrite, nitroglycerin, chloral, asafœtida, valerian, and serpentaria. Why the platitude that "strychnine stimulates the circulation generally"? On page 624 arsenic is recommended for cerebral anemia, and on page 625 it is recommended for cerebral congestion. What is "cholera simplex"? (page 631). The treatment recommended is camphor, salol, copper salts, arsenic, chloral, morphine, lead, calumba, ipecac, and cajuput oil. On page 665 thirty-five drugs are mentioned for use in dysmenorrhea, including arsenic.

Again the reviewer asks, why can not books on therapeutics be made modern as are textbooks on other subjects?

FRENCH MEDICINE

Précis de Pathologie Medicale. Tomes I and II. Par Fernand Bezancon et Andre Philibert. Paris: Masson et Cie., Editeurs, 1926. Pp. 539 and 646.

It is very unfortunate that the average physician in America does not read French. For many years, and greatly to its profit, American medicine followed very closely upon German traditions, but there is a peculiar quality in the teachings of the French school —a quality of cleanness, sanity, and common sense, which is sometimes missing from the German, and the whole mental approach is different. Any physician who wishes to practise his French, or any intern who has evenings not occupied by patients, can most profitably read these two small volumes of condensed medical text, which lie midway between the quiz compend, that invaluable aid which has enabled many a third grade student to escape the mortality of the examination hour, and the large system of medicine, which contains so much that it can only be used for occasional reference. These little books are short, beautifully written, well illustrated, and profitable for anyone to whom the language is not a complete bar.

AUTOBIOGRAPHY OF A COUNTRY DOCTOR

Sixty Years in Medical Harness, or The Story of a Long Medical Life, 1865-1925. Illustrated. By Charles Beneulyn Johnson, M.D. New York: Medical Life Press, 1926. Pp. 333.

This informative and entertaining volume is dedicated to "that ever serviceable but now vanishing member of the medical profession, the old time family doctor." Perhaps a citation of the author's foreword will serve better than anything else to give an idea of the contents of his book. "Sixty Years in Medical Harness," he writes, "is a simple narrative of the experiences and observations of an everyday country doctor who, on the one hand has endeavored to be as frank in naming his mistakes and failures, as on the other to note some of his successes and achievements. During the period covered by this narrative, namely, the last third of the nineteenth century and first quarter of the twentieth century, a complete revolution has occurred in the science and art of healing, due to the many advances and discoveries in the field of medicine. To keep pace in some measure with this revolution, and to take note of the various advance and discoveries, has at all times been in the mind of the writer, but despite his ideals he is conscious that much that he has written will not measure up to the highest standards, and for this and the narrative's many other shortcomings the writer craves the generous forbearance of the reader."

Thus simply, sincerely, and over modestly the doctor tell his tale, from which it will be possible to quote only a few of the very interesting and often humorous passages with which it is replete. In 1868 Dr. Johnson started his medical career in the village of Chatham, Ill. "As there was no one in the little town who had the skill to paint a sign for me, I proceeded to cut with my pocket knife the letters of my name from pieces of a cigar box, and these, when glued onto a board, and painted over, looked quite artistic. No one but an expert in such things would ever have believed this to be the work of an amateur!

"I shall never forget my first patient, his name was Phelps, and he had hematuria, and received a good deal of treatment from me before he finally recovered. However, for all my pains and trouble I got nothing, as he was a member of the great family of Dead Beats, whom doctors have reason to know so well."

Besides these entertaining personal and autobiographical bits which add so greatly to the entertainment of the reader, *Sixty Years in Medical Harness* is an excellent history of medical conditions and progress through the years covered, namely, from the time of the Civil War to the present time, and also a document of unusual value on the social life and social conditions of the same period. Some of these more serious chapters are entitled Medicine in 1868, How People Lived in the Sixties and Seventies, A Veteran Medical Society and Some of Its Characters (the Æsculapian Society of the Wabash Valley), Medicine in the Eighties and Nineties, The Alcohol Problem, Tuberculosis, My Medical Library; Grip, the Great Pandemic of the Late Eighties and Early Nineties; Flu, the Great Pandemic of 1918-19; and Medical Societies. The volume contains a number of reproductions of portraits of early physicians, which are extremely rare.

Dr. Victor Robinson in his introduction to the volume outlines this octogenarian autobiographer's work and character in a very telling manner. In speaking of some letters recently received from him, Dr. Robinson writes: "They are so human and humorous, they exhibit such mental balance and physical vigor, that it is difficult to believe they were typed by fingers which first touched the world over eight years ago—Dr. Johnson as a rule is his own stenographer. . . . The entire autobiography is written in a frank, simple and sincere style, and constitutes a valuable contribution to the medical history of the period."

BIOLOGICAL TABLES

Tabulæ Biologicæ. Volume II. Edited with the collaboration of 90 contributors by C. Oppenheimer and L. Pincussen. W. Junk, Berlin 15. 4 Bände—mit ausführlichem Index—in Lexicon-Octaa, umfassend uber 2000 Seiten auf holzfreiem Papier mit zum Teil colorirten Tafeln und zahlreichen Text-Figuren.

For a long time there has been in existence very complete sets of tables of physical standards, but there has been lacking a similar collection of chemical and physical observations whose interest is chiefly for the biologist. This want is being met by the *Tabulæ*

Biologicæ, volume 2 of which has just appeared. This includes many data concerning the thermochemistry of living creatures, a large section on the physical chemistry of the ferments, data on radiation, including light, x ray, and radium, and a long series of tables grouped under biophysics, but containing a most varied assortment of observations, from nerve-muscle reactions to the influence of position on the leucocyte count. The book is one which will inevitably be found on the shelves of every laboratory of pathology and biochemistry.

CORNELL UNIVERSITY REPRINTS

Cornell University Medical Bulletin. Volume XV, Number 2, October, 1925. Published by Cornell University, 477 First Avenue, New York City.

This volume contains reprints from the Department of Medicine of Cornell University collected during 1924-1925, which combine to make an extraordinarily interesting ensemble. A fair share of the papers is devoted to the study of various aspects of diabetes and metabolism. A good many of these have already been abstracted in the MEDICAL JOURNAL AND RECORD.

Medicoliterary Notes.

During Germany's health week, which extended from April 18th to 25th, the press, stage, screen, platform and pulpit aided in passing on education to both young and old in matters of personal and public health. Mother Goose even was requisitioned to do her bit by supplying illustrated passages encouraging the young to brush teeth, wash necks, go to bed early, and do other hygienic things.

* * *

Giovanni Papini, author of the *Life of Christ* which aroused such a sensation when it was published, is reported to be preparing a new book with a Biblical basis, which is to be called *Adam,* and which will embody Papini's views on the creation of the world. The author is said to be working also on an opera to be entitled *The Discovery of the World.*

* * *

The issue for December 18, 1925, of *Public Health Reports,* gives the prevalence of notifiable diseases in the various states during the year 1924. The number for December 25 contains the tenth revision of the United States Pharmacopoeia.

* * *

Insulin is derived from the pancreas of freshly killed animals, but it is not confined to pancreas alone. It is found, for example, in the muscular tissues, although in relatively minute quantities. Professor Brugsch, of Berlin University, discovered that insulin is widely distributed among living organisms, including plants, especially where starch is formed. Professor Brugsch then tried to discover the method by which the vegetable insulin could be extracted. He has been successful, and insulin extracted from acorns by his method is ready to be placed upon the market. This vegetable insulin will be concentrated in tabloid form so as to be taken perlingually. . . . Tabloids of highly concentrated insulin, known as insulingual, from the pancreas of animals have been on the market for some time, but the price is almost prohibitive; insulin derived from acorns by Professor Brugsch's method will be exceedingly cheap.—*Manchester Guardian Weekly.*

* * *

The woes of an organist in the village of Steeple Barton, Oxford, have been considerably lessened by the removal from the church organ of a swarm of bees and thirty pounds of honey, three umbrellas and a number of carefully written sermons.—*N. Y. Evening Post.*

* * *

As a part of a determined war to oust mosquitoes, British sanitary authorities have established along a strip of the south coast from Poole to Brighton more than seventy collecting stations to carry out observations on the flight of the salt water mosquitoes which infest that district. The work is conducted as a part of the activities of the new Mosquito Control Institution at Hayling Island, which, when completed, will include a research laboratory, a demonstration museum, a photomicrographic room, a drawing office, and a workshop.—*Nation's Health.*

* * *

Neglect of precautions against fire in public institutions in the United States is indicated by the fact that during 1924 fire damage of more than $10,000 took place in each of 599 public institutions, the total loss being nearly $60,000,000, or about 10.3 per cent. of the nation's fire waste for the year.—*Greater New York.*

* * *

The twenty-second annual report of Bellevue and Allied Hospitals of New York City, and the fortieth annual report of Montefiore Hospital, New York City and Bedford Hill, have recently been issued.

* * *

At its recent annual meeting the Kings County Homeopathic Society elected the following officers for 1926; Dr. Royal A. Abbott, president; Dr. Herbert S. DuCret, vice-president; Dr. Farrand B. Pierson, second vice-president; Dr. Clarence J. Ohlbaum, secretary; Dr. Remick C. Eckhardt, treasurer; Dr. J. Alexander Stewart, necrologist; Dr. Charles A. Brown, Dr. George S. Ogden, Dr. Chester A. Peake, Dr. Walter S. Rink and Dr. Justus G. Wright censors.

* * *

Dr. William P. Healy, recently elected president of the New York County Medical Society, was guest of honor at a dinner given by the New York Celtic Medical Society at the Waldorf Astoria, on February 5th. Among the speakers were Judge Alfred J. Talley, Dr. Nathan B. Van Etten, Dr. Thomas H. Curtin, and Dr. Michael J. Horan, who presided.

A survey has just been completed by the Hospital Information Bureau of the United Hospital Fund which shows that the largest private hospital in New York City could not accommodate the out of town patients alone who are treated in the nonmunicipal hospitals in a year. The report states that "a study of the records of seven representative hospitals in Manhattan showed that twelve and four-tenths per cent. of all patients treated in 1924 lived outside New York City. This includes a large special hospital where twenty-five per cent. of the patients come from outside the city, attracted by its excellent reputation, as well as the down town hospitals, serving commuters mainly, where as high as 15 per cent. of the patients are nonresidents."

* * *

Titania's Palace, a toy house which it took more than twenty years to build, has been brought to this country by its builders, Lord Nevile and Lady Wilkinson, to be shown at the Philadelphia Sesquicentennial Exposition and later in the larger cities of the United States. The proceeds of its exhibition will be used for building a new wing for the London Hospital for Crippled Children. Titania's Palace, not to be confused with the Queen's Dolls' House, was built in Dublin and is filled with many tiny and exquisite samples of Irish craftsmanship.

* * *

The recently published report of an investigation states that engine drivers and firemen usually become gray between the ages of thirty and forty.

* * *

The fact that genuine diamonds, when exposed to ultraviolet rays "light up" and—to quote the words of a police expert—take on the appearance of "beautiful blue lamps," while faked diamonds remain lifeless and dull when subjected to the same test, has enabled the police in numerous instances to detect fraud and to set on foot inquiries leading to the early arrest of the diamond "fakers." The knowledge, too, that many aniline dyes "light up" vividly when exposed to ultraviolet rays has helped the Berlin police to track down burglars who, when getting away from a house after a robbery, had left behind threads which had been detached through the incidental rubbing of their clothes against doors or window frames. In such cases, where dyed materials are involved, it has been proved that a quartz lamp is more serviceable for purposes of examination than a microscope.—*Modern Sunlight.*

Abstracts from Current Literature

GASTROENTEROLOGY

The Fate of Sutures as Observed in Intestinal Anastomosis and in the Healing of Wounds.—Frederick Leet Reichert and Emile Holman (*Bulletin of the Johns Hopkins Hospital,* March, 1925) present a study of thirty-eight experiments in which Dr. Halsted's blind end circular suture of the intestine was performed, and further observations were made to determine the fate of sutures in the different types of intestinal anastomosis in common use. The results obtained emphasize the importance of gentleness and care in handling tissues. The authors state that silk sutures used in intestinal anastomosis migrate either to the peritoneal surface and are covered only by a transparent layer of endothelial cells, or to the lumen of the bowel, into which they eventually drop off and are lost. When the sutures do not enter the mucosa they migrate toward the peritoneum. If the mucosa is pierced they slough into the lumen. The presence or absence of infection along the stitch determines in which direction the sutures will travel. Absorbable material would seem to be superior when through-and-through sutures are required. The flange of inturned bowel soon disappears when trauma or soiling does not complicate, but persists, with long delayed fibrous healing when either or both of these factors are added. The degree of omental adhesions at the site of anastomosis is also dependent upon trauma and soiling. No difference was noted in the healing about a lateral anastomosis when a single row of interrupted mattress silk sutures or a double row of continuous catgut sutures was used. Sutures used in the closure of abdominal wounds, when applied so as to constrict the tissues which are included, invariably produce defects in the anterior sheath. Sutures applied so loosely as just to approximate the edges of the wound did not injure the tissues. The vertical figure of eight suture is better than the horizontal figure of eight. Simple vertical sutures are as efficient as the vertical figure of eight suture.

Extravasation of Bile.—Z. Cope (*British Journal of Surgery,* July, 1925) advises that the treatment of biliary extravasation is by operative measures. The bile must be allowed to escape from the peritoneal cavity so far as is possible, and any tension in the biliary passages must be reduced. In a patient who is very ill, merely drainage of the peritoneum and of the gallbladder is called for. If the biliary ducts appear normal and the bile appears to be escaping from the gallbladder, it is a natural procedure to remove the gallbladder, provided the patient's condition warrants it. Any stones in the common duct should be removed.

With the present late coming of these cases, however, the mortality is very great. Six out of ten of the patients mentioned in this paper succumbed. It is quite clear that the curing of acute abdominal disease depends chiefly upon early diagnosis.

Intussusception Due to Meckel's Diverticulum.—W. E. Lower (*Annals of Surgery,* September, 1925) offers two new cases of this unusual complication and reviews its symptomalogy as follows: 1. Repeated attacks of partial obstruction before the culminating attack which leads to surgical intervention, in some cases these repeated attacks being sufficiently mild and extending over a period of time to suggest chronicity. 2. Absence of blood in the stools. 3. Frequent lack of a palable tumor. 4. Lack of local tenderness.

The presence of a diverticulum and a beginning intussception should be suspected from these symptoms in young adults; and in older patients who have had recurrent attacks of right sided abdominal distress, with or without bloody stools or diarrhea; with or without a palpable tumor; with or without tenderness to the right of umbilicus. In such a case, if no other cause of the condition can be demonstrated, an exploratory operation should be performed, for provided a diverticulum is present the catastrophe of intussusception may occur at any time. If it is not present, no more harm is done by the exploratory operation than is done by the removal of the chronic appendix because of the presence of the train of symptoms which suggest a chronic appendicitis with the ever present danger in that case also, of an acute catastrophe. Moreover, just as the appendix is routinely removed in the course of an abdominal operation in order that the source of danger for the future may be obviated, it would appear well to consider whether or not one should look for a diverticulum in those cases in which an exploratory operation is performed for suspected appendicitis and the appendix is found to be normal.

Pancreatic Cysts.—H. Roth (*American Journal of Surgery,* Vol. XXXIX, No. 11) reports on two cases of this complication, discussing their etiology, varieties, and diagnosis.

Cysts of the pancreas require surgical treatment. Treatment by aspiration should no longer be practiced, nor is it necessary to do a two stage operation. Drainage through the loin may occasionally be indicated. If the cyst has a small pedicle it may be completely removed without much danger, but as a rule partial or complete excision of the cyst is rarely practicable or safe owing to the danger of hemorrhage from separating dense adhesions and the danger of injuring the pancreas. The safest operation and the one most suitable in the majority of cases is evacuation of the fluid and drainage through a laparotomy incision, after isolating the cyst from the free peritoneal cavity. The operation is done by exposing the bulging tumor through a median or lateral laparotomy. The cyst is exposed by dividing the various layers of peritoneum which lie in front of it.

These will vary according to which one of the three positions the cyst may occupy. If the cyst lies below the greater curvature of the stomach, the two layers forming the gastro colic omentum and the posterior parietal peritoneum have to be divided to reach the cyst wall. If the cyst lies below the liver and above the lesser curvature of the stomach, the two layers of peritoneum forming the gastrohepatic omentum and the posterior layer of the parietal peritoneum have to be divided. After the cyst wall is reached and the general peritoneum has been protected by flat laparotomy pads, the cyst is punctured, and the fluid is evacuated by suction. The puncture is enlarged sufficiently to permit complete emptying and inspection of the cavity. As much of the cyst wall as can be without danger should be excised. The edges of the opening in the cyst wall are then sutured to the anterior parietal peritoneum, thus marsupializing the cyst. A large drainage tube is introduced into the remaining cavity and the rest of the abdominal incision is closed in layers. If possible the drainage tube is connected with a bottle to protect the skin from irritation from the discharging fluid.

Frequent changes of dressing are necessary and the skin must be protected against irritation. The cavity is obliterated by filling up with granulations. Occasionally a fistula may persist for a long time, or after it is closed the cyst may reform. Roentgen ray treatment and an antidiabetic diet have been recommended to hasten closure of the fistula.

Gastroduodenal Ulcers.—W. M. Brickner and H. Milch (*American Journal of Surgery,* Vol. XXXIX, No. 11) present and discuss eight cases of different types of these ulcers, giving the following suggestions as to method of treatment:

In performing gastroenterostomy we do not turn or twist the jejunum to secure "isoperistalsis." Tracing it from its emergence into the peritoneal cavity at the fossa of Treitz, we merely bring the jejunum, without tension but also without a loop, directly over to the right for its attachment to a relatively non vascular site on the posterior wall of the stomach, near the greater curvature and about two and a half or three inches from the pylorus, which surface has been pushed through a tear made in the transverse mesocolon. We think it desirable to secure, by separate ligatures or by a whipstitch, cut vessels in both stomach and jejunum. The anastomosis is made with an inner Connell suture and an outer Cushing suture of chromicized catgut. To date, none of the patients upon whom we have ever performed a gastroenteric anastomosis has developed a jejunal or gastrojejunal ulcer, so far as we know.

In the matter of treatment of a fixed hour-glass contracture the obvious indication is to abolish the stenosis. This may be done either by performing a gastrogastrostomy, of the type suggested by Finney for pyloroplasty, or by resecting the portion of the stomach distal to the stenosis and then reestablishing the gastrointestinal continuity by gastrojejunostomy. In such a case as this, with a recurring ulcer, resection is much the better procedure.

In perforated ulcer we call attention to the employment of a suction apparatus to remove the fluid at operation. This is our routine practice in cases of peritonitis, ectopic pregnancy or other condition in which any considerable amount of pus, blood or fluid is to be dealt with. The procedure is more thorough and less traumatising than sponging. The Kenyon-Pool suction tip is inserted into one pocket after another, by the assistant, while the operator is engaged in dealing with the lesion itself. Suction evacuation is thus time-saving and therefore, in these often desperate cases, it is sometimes life-saving.

The operations proposed for perforated ulcer are: Simple suture, excision and suture (in either case reinforcing the line of closure by attaching omentum—especially if the tissues are friable), suture, or excision and suture and gastroenterostomy, and primary resection (usually pylorectomy). Closure of the opening and infolding by sutures is the most commonly performed operation; and the point most under discussion is whether or not gastrojejunostomy should be associated with this routinely.

Some surgeons urge that gastroenterostomy should be included in the operation; others equally earnestly advise that it should not be done as a primary procedure. We do not think either conclusion should be accepted as a hard and fast rule. When the performation is dealt with early, if there is little contamination of the peritoneum and the patient's condition is good, a gastrojejunostomy may be added without unduly increasing his hazard; and especially if, under these circumstances, the infolding appears to have greatly compromised the pyloric outlet the surgeon may well elect to include the anastomosis. When there is much soiling of the peritoneum and, especially, when there is evidence of peritonitis or and when, as is so often the case, speed is an important consideration, gastrojejunostomy adds too much to the patient's risk. The stenosis of the pylorus by suturing is seldom as great as it appears and, too, it soon yields; and if the need for gastroenterostomy becomes evident it can be done, more safely, later on, when the patient has recovered from his primary shock and the field is clean.

PEDIATRICS

Acrodynia.—F. C. Rodda (*American Journal of Diseases of Children,* August, 1925) draws the following conclusions from a clinical study of seventeen cases: Acrodynia is a disease of infancy and early childhood, which is preceded or accompanied by an upper respiratory infection and which presents three groups of symptoms in varying degrees and combinations: 1, general: anorexia, loss of weight, weakness; 2, nervous system: hyperirritability, sleeplessness, paresthesia, anesthesia, loss of reflexes, paresis, photophobia, and 3, dermatological: hyperhidrosis, miliaria, desquamation, erythema, swelling, cyanosis, coldness of hands and feet, alopecia, ulceration and loss of teeth. At first the condition was erroneously thought to be a deficiency disease, but it more probably is the result of a focal infection, usually in the tonsils and the adenoids. Although the dermatological findings are pathognomonic, the disease should be suspected in cases of unexplained, persistent hyperirritability and hyperhidrosis; removal of tonsils and adenoids at this stage may abort the disease. In the series studies, early recognition of the disorder and prompt removal of tonsils and adenoids has been followed by speedy recovery in all patients.

Van den Bergh Test for Icterus in Blood of Infants.—Clifford G. Grulee and Annette Mebane (*American Journal of Diseases of Children,* August, 1925) found that their results agreed quite well with those of other investigators who have studied the van den Bergh reaction in simple icterus neonatorum. Both from the umbilical blood and from the blood serum of the infant after the jaundice had developed only the indirect reaction was obtained. In three cases of jaundice in the course of acute respiratory infections, and in one case following the administration of neoarsphenamin, the reactions were all indirect, which findings agree with the contention of van den Bergh. In two cases of catarrhal jaundice only indirect reactions were seen; in one case of obstructive jaundice the results were so irregular as to be of questionable value. The evidence presented is such as to raise a doubt as to the value of the van den Bergh reaction as a method of differentiating between obstructive and non-obstructive types of jaundice in infants and in young children.

Rickets in Infants: Treatment with Irradiated Milk.—Benjamin Kramer (*American Journal of Diseases of Children,* August, 1925) reports that in a series of eight patients with active rickets, the administration of irradiated milk produced healing in every case. This was demonstrated at the end of the third week and was marked at the end of the fourth weak. The chemical changes in the blood following this treatment were identical with those previously reported, which followed the administration of cod liver oil to rachitic children or the exposure of such children to ultraviolet rays or to sunlight. Irradiated milk feeding induces a marked retention of both calcium and phosphorus.

The Roentgenogram in Early Scurvy.—K. F. Pedkan (*American Journal of Diseases of Children,* August, 1925) assert that the essential points in the roentgenogram of a well developed case of scurvy are the following: 1, A finely irregular, broadened, well calcified epiphyseal line; 2, a small spur at the lateral edge of the epiphyseal line; occasionally dislocation of the entire epiphysis; 3, an area of decreased density (scurvy line) immediately back of the epiphyseal line, which represents lack of calcification of the newly formed spongiosa; 4, a very thin cortex, often merely a narrow white line; 5, glasslike transparency of the shaft; no trabeculations as in normal bone or in rickets; 6, a broad, finely irregular white edge on the epiphyseal center of ossification of the long bones.

Less advanced cases of scurvy show practically all of the previously mentioned changes except the lateral spur of the epiphyseal line, which is apparently the las taddition to the scorbutic damage in the bones. The borderline case of scurvy usually shows only three of the characteristics before mentioned: the broadened epiphyseal line, the dense shadow around the center of ossification of the epiphysis and the absence of trabeculations in the shaft. The diagnosis of scurvy can with certainty be made on these three signs, even in the absence of the much abused scurvy line.

The author's conclusions are as follows:

1. The ground glass appearance of the shaft, which is due to the disappearance of trabeculæ, is an important and hitherto underestimated roentgenographic sign of scurvy.
2. We can support the claim that the edging of the epiphyseal centres is a constant and reliable sign of scurvy.
3. The combination of broadened epiphyseal line, edging of the epiphyseal centre and disappearance of trabeculations in the shaft is pathognomonic of this disease.
4. Scurvy can be diagnosed by the roentgenogram before any of the accepted clinical symptoms (pain, hemorrhagic manifestations) have appeared.

Avitaminoses in Breast Fed Infants.—Geza Petényi (*Monatsschrift für Kinderheilkunde,* August, 1925) states that avitaminoses may also occur in infancy with breast feeding, being most probably due to a deficiency of the D factor in the milk. This can be cured by the administration of minimal amounts of vegetables. Clinically, this takes the form of a retardation of development, followed possibly by a slight anemia.

When young eczematous and breast fed children do not flourish it is advisable to try the addition of small amounts of vegetables to the usual food. It is not proper to persist with an exclusive breast feeding in these cases, as there are cases in which the cause of the failure of development is not to be attributed to the exudative diathesis, but to the qualitative insufficiency of the mother's milk. The same claim also holds in the cases of retardation in debilitated or premature children.

Scarlet Fever: with Special Reference to Susceptibility as Determined by the Dick Intracutaneous Test.—W. A. Brown (*British Journal of Children's Diseases,* July-September, 1925) in the Grove Fever Hospital, London, gives some results obtained from testing 487 cases for susceptibility to scarlet fever using the Dick test.

Concerning the technic of the test the following methods were pursued. The skin on the anterior surface of the forearms was carefully cleansed with methylated spirit. Using

an ordinary hypodermic syringe and fine gauge needle. 2. c. c. of the diluted toxin was introduced intradermically into the left arm. As a control the same procedure was carried out on the right arm), 2 c. c. of the same dilution of toxin previously heated for forty-five minutes at 95° C. being used. Upon commencing investigations a practice was made of observing the reactions at various periods from six to thirty-six hours after injection. Although in some cases the reactions could be interpreted accurately at the end of twelve hours, the author found that the best time for reading results was twenty-four hours after injection. Positive reactions usually began to appear in from eight to twelve hours, reaching a maximum intensity in twenty-four hours and subsequently fading rapidly. At the end of forty-eight hours from the time of injection nothing was visible, except in a few cases which gave strongly positive reactions, and in which the area of redness was faintly visible after forty-eight hours. In all the cases tested with 1:6000 dilution swelling only occurred once and pain was never present. Desquamation was also absent, except in some cases mentioned in the paper. Pseudoreactions were not very common. In the first 430 cases tested a 1:6000 dilution of toxin was used with a corresponding control. Subsequently, a 1:1000 dilution was employed in a further series of tests.

The body of the experiment pointed to various conclusions. 1. The Dick intracutaneous test is an index of susceptibility and immunity to scarlet fever. 2. When a patient, who gives no previous history of disease, shows a wellmarked positive skin reaction, there is strong presumptive evidence that his or her immunity to scarlet fever is slight or absent. 3. The Dick test is a valuable aid to diagnosis, and a strongly positive skin reaction in the first 48 hours of a scarlatiniform eruption would lead one to hesitate before making a diagnosis of scarlet fever. 4. When a patient, who has recently shown a positive Dick reaction, develops a scarlatiniform attack, the reappearance of the red area at the site of original inoculation is confirmatory of a diagnosis of scarlet fever. The observation of Zingher was not confirmed that an area of pallor appears at the site of previous injection in a positive reactor who contracts the disease. 5. The results of the test demonstrate that age susceptibility is highest at a period before the children commence to attend school, whereas age incidence is greatest during the first few years of school life. This shows that immunization if adopted as a prophylactic measure in State medicine, should be carried out in the first few years of life. 6. The well recognized fact that an attack of diphtheria increases the patient's susceptibility to scarlet fever is confirmed by the test. 7. The use of different dilutions of toxin may show widely divergent results. The use of a 1 to 6,000 dilution of toxin seems to underestimate the susceptibility, while the use of a 1 in 1,000 dilution tends to over-state the incidence. 8. A more reliable method of standardizing the toxin is necessary in order to obtain a uniformity of results. 9. Further investigations to elucidate the nature of the atypical forms of scarlet fever are necessary before a satisfactory explanation can be proffered of some of the apparently anomalous results of the test in this type of case.

The investigator offers some suggestions for improving the present technique of toxin standardization, namely, the use of a standard strain of streptococci procured from typical scarlet fever patients. The growth of this strain for a definite time on definite media. The employment of a standard method of preparing the toxin from these cultures. The adoption of a definite clinical conception of what is to be regarded as scarlet fever.

A Comparison of the Kahn with the Wassermann Test.—Mildred H. Faupel (*Bulletin of the Johns Hopkins Hospital,* September, 1925) reports the results on four hundred patients in which the Kahn and Wassermann tests were done in parallel. For the latter test, a cholesterinized beef heart antigen was used, and in the majority of cases, waterbath fixation, the rest being in the icebox. Of these, 90.2 per cent. showed absolute agreement, 3.8 per cent. good relative agreement, 5 per cent. partial agreement, and 1 per cent. absolute disagreement. The coefficient of correlation for the whole series was found to be 0.79. The method is comparatively simple and the reaction is completed within five to thirty minutes after mixing serum with antigen. The test is of especial value in cases in which the rapidity of obtaining results is an important factor. The test has not been found applicable to spinal fluids by the author.

Brain Tumors in Children: Their General Symptomatology.—MacDonald Critchley (*British Journal of Children's Diseases,* December, 1925) discusses the general symptomatology of brain tumors in children, without touching on questions of differential diagnosis, localization, prognosis or treatment. The paper is based on a fourteen year contract with admissions to the National Hospital, Queen Square. Only those cases are included of tumor occurring in children before the seventeenth year. Dr. Critchley finds the phenomenon of remission particularly characteristic of tumors occurring in childhood and believes it to be suggestive of tuberculomata situated in the pontocerebellar regions.

Intrathoracic Tumors in Children.—Hugh L. Dwyer and Ferdinand C. Helwig (*American Journal of Diseases of Children,* December, 1925) report an interesting occurrence of intrathoracic osteochondrosarcoma in a boy aged twelve years. The tumor originated from the inner aspect of the fifth rib, almost filled the right thoracic cavity, producing atelectasis of the right lung and displacement of the heart and mediastinal structures.

Effect of Prepuberty Castration on Subsequent Cancer Implantation.—James B. Murphy and Ernest Sturm (*Journal of Experimental Medicine,* August, 1925) state that male and female mice castrated during the first seven weeks of life and implanted with cancer at later periods show a resistance definitely higher than do intact animals of the same age. This increased refractiveness is evident at three months after the operation but is more pronounced at eight months to a year. Even castration in early adult life seems to increase the refractory state to later cancer inoculation. On the other hand, adult mice inoculated within a week after castration show slight if any evidence of marked increased resistance.

Dick Test for Susceptibility to Scarlet Fever.—Claude B. Ker, J. E. McCartney, and J. McGarrity (*Lancet,* January 31, 1925) find that there appears to be no difficulty in obtaining hemolytic streptococci from the throats of patients in early cases of scarlet fever, from which may be prepared filtrates which, when suitably diluted, may be safely injected intradermally and which cause a local reaction in persons who are presumably susceptible to scarlet fever, or who are actually suffering from its early manifestations. This reaction is not liable to occur in the vast majority of persons who have already had scarlet fever, and in scarlet fever patients tends to become negative as convalescence advances. As regards those individuals who, not having had scarlet fever, nevertheless give negative reactions, it may be assumed that they have, as in the case of diphtheria, acquired immunity by exposure to subinfective doses of virus at some previous period of their existence.

The chief difficulty at present is to standardize the toxin. If it is too weak the results will be reliable, the proportion of positive reactions being unduly low, as the authors found in their series of cases. This difficulty can to some extent be overcome by carefully comparing the results of different filtrates on known human reactors. It is probably wise, when a satisfactorily acting filtrate is obtained, to use it exclusively. In the hands of the authors, this precaution promises to bring better results in the future.

Antitoxin Intraperitoneally.—Joyn A. Toomey, Otto L. Goehle and Carl C. Dauer (*American Journal of Diseases of Children,* February, 1925), compared fifty cases of diphtheria treated by intraperitoneal injection with other methods of antitoxin in administration. They found the intraperitoneal injection method a safe and simple one. They showed that antitoxin may be used intraperitoneally, just as it is received from the commercial house, undiluted with saline solution. This method of injection is not recommended for all cases of diphtheria, but it seems to be the method of choice in cases of toxic myocarditis where the shock associated with intravenous injection might very well be avoided by intraperitoneal injection, and in infants and children who have had diphtheria for more than two days and who have poor veins. It is a comparatively safe method, but proper surgical precautions must be practiced before puncturing the peritoneum. The authors have followed Blackfan's technic.

PHYSIOTHERAPY

Quantitative Data in Tissue Reactions to Ultraviolet Radiations.—P. R. Peacock (*Lancet,* August 22, 1925) draws the following conclusions from his experiments:

1. Since the skin surface is rendered visible by fluorescence, when only the invisible ultraviolet rays fall upon it, it is obvious that a greater or less amount of the incident rays is being dissipated at the skin surface as light and is consequently incapable of acting on any deeper structures.

2. Since fluorescence commences directly the skin is exposed to ultraviolet rays, whereas pigmentation only occurs as a result of considerable exposure, it is logical to suppose that, in fluorescence, we have a more immediate protection from excessive radiation, as far as ultraviolet rays are concerned, than in pigmentation.

3. Since all the fluorescent substances examined, as well as the melanin which causes pigmentation, show marked absorption of ultraviolet rays, and since fluorescence and pigmentation always seem to vary inversely to each other, it might be interpreted that pigmentation marks the failure of fluorescence to protect the structures of the cutis vera from excessive radiation. This is substantiated by the experiments on artificially increased fluorescence, where no pigmentation follows exposure.

4. If pigmentation of the patient is aimed at as a standard of successful treatment, this is tantamount to producing deliberately in the patient a natural and efficient protection against the very source of treatment employed.

5. The pigmentation must be regarded as an indication that the penetration of the rays has not been prevented by fluorescence at the skin surface. If pigmentation could be avoided without hindering the penetration of the rays to the cutis vera it might prove more beneficial.

6. By employing the maximum dose which will on each application just fail to produce pigmentation, and, by separating the exposures by the minimum time interval necessary to avoid the cumulative effect, it should be possible to get equally good, if not better, therapeutic results in a shorter time.

Therapeutic Value of Light.—C. E. M. Jones (*British Medical Journal,* September 19, 1925) states that artificial light treatment is employed as a substitute for heliotherapy when natural sunlight is not available, either owing to climatic conditions or when suitable sites for the use of heliotherapy are lacking, as in congested areas in large towns. Much valuable work is done in light clinics by giving artificial light baths to rickety, debilitated, and pretuberculous children. In the treatment of nonpulmonary tuberculosis artificial light treatment differs from heliotherapy in one important particular. Whereas in heliotherapy it is the general effect of light that is important as compared with the local action, in the artificial light treatment of these cases the part played by local treatment is of far greater importance, though here also it should always be combined with general treatment.

Either the carbon arc lamp or some form of mercury vapor lamp may be used. Each has its advantages. The former more closely resembles natural sunlight, and possesses greater power of pigmentation than the mercury vapor lamp. On the other hand longer exposures are required. A commencing dose of twenty minutes to a half an hour might be given with a carbon arc lamp, whereas three minutes with a mercury vapor lamp would suffice. The arc also gives out a fairly considerable amount of heat, which is apt to become exhausting to young or debilitated patients, and therefore the mercury vapor lamp is sometimes preferable. The author prefers the arc for the purpose of general light baths. The arc lamp may also be employed with caution in the treatment of cases of the nonpigmenting type which cannot be exposed to natural sunlight. The cases will often acquire a certain amount of pigmentation, the protective action of which will enable them to tolerate some exposure to natural light, with its corresponding benefits.

Cases of lupus, scrofuloderma, skin tuberculosis, glands in the neck, sinuses, etc., are greatly benefited by the local treatment by light relatively rich in ultraviolet rays. Lupus in the ulcerative stage is advantageously treated by the mercury vapor lamp; when the ulceration has healed the treatment must be completed by the Finsen-Ryen lamp, which is usually essential for the final eradication of the disease. Scrofuloderma may be treated by the mercury vapor lamp or the tungsten arc; skin tuberculids by the mercury vapor lamp; glands in the neck, more especially those of a multiple nature and accompanied by periadenitis, are greatly benefited by the tungsten arc. The Kromayer water cooled mercury vapor lamp is useful in certain stages of the treatment of lupus. The quartz rod applicators are very helpful in the treatment of lupus in such situations as the interior of the nose, the gums, rectum, vagina, etc. There is an advantage in the combined general treatment with all forms of local light.

Light treatment is contraindicated in nonpigmenting persons, in pyrexial cases of marked amyloid disease, the acutely ill, the very young and the aged. In unsuitable cases the light treatment produces depression instead of stimulation. Depression is also produced by overdoses in cases otherwise favorable.

Intratracheal Use of Iodipin for the Röntgen Diagnosis of Respiratory Organs.—Walter Landau (*Klinische Wochenschrift,* September 24, 1925) prefers the subglottic route, the pharynx and larynx being anesthetized as in endolaryngeal procedures. Patients who have a marked secretion of mucus and an irritative cough are prepared with morphine and atropine. With a laryngeal syringe, the cannula of which is long enough to reach under the glottis, two c.c. of a two per cent. cocaine solution are injected into the trachea. After a short pause, the iodipin is injected under vision with a laryngeal mirror. The iodipin must be previously warmed so as to make it a thinner fluid, and ten to forty c.c. may be used. According to the region to be examined, the injection may be made in the sitting, dorsal, or lateral position, and possibly with lowering of the upper part of the body. The exposure to x rays should be made as soon as possible after the injection of the contrast medium, as the latter soon spreads, is coughed up, and the picture becomes less distinct.

The author draws the following conclusions from his own experiences and the literature:

1. Iodipin appears to be just as good, as regards its manner of action and the ease with which it is borne, as lipiodol.

2. Although the main mass of the oil is coughed up, there is very probably a resorption of a certain portion of it, the rapidity and amount of which is not yet definitely determined.

3. In agreement with other authors, the use of iodipin for a roentgenographic contrast examination is a considerable improvement in the diagnosis of bronchiectasis.

4. The demonstration of hollow cavities can be expected only in isolated cases, and a negative finding does not prove anything; however, a positive finding in doubtful cases may be of a decisive nature and should always be looked for.

5. In case the contrast oil does not penetrate to certain sections of the lung, especially in the apical regions, the occlusion of these particular portions of the bronchi cannot be assumed. Even with the different postures it is not always possible to inject with certainty a definite portion of the lungs, especially if only a single examination can be made.

6. This method is certainly well suited for the diagnosis of bronchocutaneous and pleuropulmonary fistulas; in such a case the injection of methylene blue into the skin fistula or the introduction of ether into the empyema cavity are valuable aids which determine the connection with the bronchial tree.

7. This method should be used only with the strictest indications. Even though clinical experiences have not shown the occurrence of any resulting injury, we must nevertheless take into consideration the histologic changes of a certain grade in the alveoli, a possibility, the importance of which must be weighed against any help that may be expected from the procedure.

Radiotherapy in Bronchial Asthma.—Gabriel Moner (*Revista de la Sociedad Argentina de Radio y Electrologia,* May 28, 1925) reports the results of radiotherapy in twenty-three cases of bronchial asthma. He believes that this measure is one of value in certain cases of bronchial asthma, and one to be tried when other measures have failed. Cure was obtained in thirty-eight per cent. of the cases.

Radiological Examination of Male Genital Apparatus by Injection of Lipiodol.—Eduardo L. Lanari and Alejandro Astraldi (*Revista de la Sociedad Argentina de Radio y Electrologia,* May 28, 1925) believe that they are the first to report the use of lipiodol for the examination of the seminal vesicles. They thing that this substance has the incontestable advantage over all other substances that it is nonirritating and does not provoke an epididymitis.

A New Method in Electrotherapy.—Theodor Bruno Weiss (*Wiener klinische Wochenschrift,* October 1, 1925) conducted some experiments with the idea of impregnating human bone with silver and silver salts with the aid of an electric current. This method of treatment offers some valuable points therapeutically in tuberculosis. A bactericidal effect is shown by the battle against the tubercle bacilli in the deep tissues through the effect of an effective chemical substance. It was found that the still undestroyed bone is impregnated with a protective substance that prevents the advance of the process. The bone that is still in the initial stage of the disease is plugged. It is also possible that there results an incitation to bone regeneration.

The experiments were conducted only on bony tissue, but it may be assumed as highly probable that the nonbony tissues (tuberculous granulations) take up more or less of the colloidal silver and are influenced in this or some other way by the bactericidal material penetrating the bone. Although these experiments are still in an experimental stage, it may well be said at the present time that this method of treatment seems to justify the hopes that it will prove useful therapeutically in bone and joint tuberculosis.

DERMATOLOGY

Eczema in Infancy Due to Protein Sensitization.—Bret Ratner (*Medical Clinics of North America,* November, 1925) presents three cases of severe eczema which were shown to be caused by protein sensitivity, and he also shows that the elimination of offending proteins effects good results.

That there may be a goodly number of eczema cases which do not respond to protein sensitization investigation and do respond to the various methods of treatment advocated by others, the author grants; such cases, however, do not, as a rule, belong to the severe refractory type referred to by the author, but rather are of the milder facial and other local types. He also agrees that there are spontaneous cures. When cases, however, resist local and general treatment, they should be studied from the viewpoint of protein sensitization; in fact, they should only be undertaken after they have been observed for a number of weeks, and do resist such treatment. Furthermore, they should not be taken unless a most complete study can be made. The cooperation of the patient is absolutely necessary for such a study. In dealing with protein sensitization in infants and children, one must never lose sight of their nutritional requirements, for without the understanding of the nutritional side only partial good can be accomplished.

Bakers' Dermatitis.—N. Howard Mummery (*Lancet,* September 26, 1925) advocates the following prophylactic measures and treatment for bakers' dermatitis. Prophylaxis includes:

1. The exclusion as far as possible from dough and pastry handling of all persons with dry skins which render them subject to chapping and cracks in winter.
2. Insisting that all minor lesions such as cracks, abrasions, and hang nails be reported at once and treated with a solution of nitrate of silver or iodine.
3. Weekly manicure on special lines, including the addition of anosol to the soap solution used for the softening of the fingernails, for workers particularly prone to contract the disease.
4. Providing all workers in contact with flour, dough, pastry, and sugar with a small towel suspended from a tape round the waist, these towels being collected and washed daily. The abolition of all roller or common towels.
5. Supplying bowls of a weak, harmless antiseptic solution, such as sodium hypochlorite, in suitable positions in workrooms, and encouraging employees to rinse their hands in this solution occasionally while at work.
6. Every skin eruption, however trivial it may appear, has to be reported to the medical officer immediately, and in all cases detected the patients are suspended from duty and treated at the factory surgery until well.

The use of Metchnikoff's ointment (subchloride of mercury thirty-three per cent. in anhydrous lanolin) has been found entirely satisfactory if applied freely, rubbed in, and covered to exclude air. When possible the evacuation of the vesicles greatly hastens healing. All cracks are painted with nitrate of silver, fifteen grains to the ounce of spiritus etheris nitrosi, before the ointment is applied. A patient so treated in the early stage generally clears up entirely in a week, but after resuming their ordinary work the patients continue to apply the ointment at night, when off duty, for a month or so in order to prevent relapses. Sometimes considerable patience is required to eradicate the disease, but the intelligent worker will at once report the appearance of a fresh vesicle which can then be evacuated antiseptically and aborted without further absence from duty.

A Special Form of Chronic Paronychia.—Joseph von Deschwinden (*Schweizerische medizinische Wochenschrift,* September 3, 1925) calls attention to the group of chronic paronychias that is not clearly defined, which is not even clearly determined etiologically. Many physicians can recall cases of chronic paronychia that have resisted all forms of specific and nonspecific therapy, as well as surgical therapy. Four such cases are reported by the author.

Treatment with tincture of iodine, iodoform, silver nitrate and balsam of Peru salve, ichthyol, salicylic plaster, chromic acid, and even röntgen and quartz light irradiation, etc., were all futile. In the less chronic cases success has been reported with hot baths and weak disinfectants in individual cases. Gray salve has also given some favorable results.

The author achieved striking results with neosalvarsan. Treatment was given twice a week when possible. The neosalvarsan powder is pushed under the nail groove with a suitably cut piece of wood, taking care that it reaches to the deep foci or small abscesses. The pains soon disappear and the reddening and swelling also recede. The symptoms may be aggravated temporarily, but soon improve under bland salve treatment. After the symptoms have disappeared and additional one or two applications of neosalvarsan will prevent recurrences. One or two applications may result in a cure.

It is believed that a small, rodshaped, gram negative bacillus with rounded corners is the excitant, as it was possible in every case to obtain a culture from the expressed secretion. The condition could be reproduced experimentally in guineapigs.

Radical Operative Treatment of Varicose Ulcers.—Gunnar Nyström (*Acta chirurgica Scandinavica,* January 21, 1925) state that varicose ulcers occur more frequently than is generally imagined and fifty per cent. of them in persons under sixty years of age. The best treatment of large callous ulcers consists in excision and skin grafting after the method of Thiersch. Recurrences set in more easily after spontaneous healing than following grafting, which fact may be due to the plane of demarcation between the epidermis and the cutis uera being different in the different modes of healing. The more radical the excision the more certain the results, and the excision should be made to include not only the ulcer itself but every trace of callous scar tissue beneath and around it down to the periosteum, in order to secure a bed of normal tissue for the graft. In following up a series of nine cases in which operation was performed, six were found healed from seven to twenty-two months after operation, two being only partially successful and one not traced.

Treatment of Internal Leishmaniosis.—Guido Izar (*Presse médicale,* March 7, 1925) states that tartar emetic, while usually highly effective in this disorder, is sometimes unavailable because it is not well borne or cannot be continued on account of renal or cardiac lesions. In a few cases, moreover, it is ineffectual. In two cases which proved resistant even to large dozes of tartar emetic the author used successfully intravenous injections of an alkaloid from *Sanguinaria canadensis,* sanguinarine sulphate, and of isoamylhydrocupreine hydrochloride. These two cases having been cured in three months, a single solution combining the two remedies was employed in subsequent cases, 0.4 gram of the first compound and 4 grams of the second being dissolved in 100 grams of distilled water. This solution is injected in doses ranging from one-fourth to two mils. The amount is increased by one-fourth mil at successive injections, according to the patients' and the manner in which the drugs are tolerated. Injections are repeated twice weekly until the enlarged spleen subsides. The gratifying results obtained justify further trial of the treatment.

Gaucher's Disease.—V. Tramontano (*Rinascenza Medica,* July 1, 1925) gives the clinical history and findings as well as the results of histopathological study of a case of Gaucher's disease or splenic endothelioma. Three excellent plates illustrate the article and the author believes that this disease is due to hyperplasia and absorption of a special substance which is found in the reticuloendothelial apparatus of the hemolymphopoietic organs.

Erythredema or Pink Disease.—The condition described by C. P. Lapage (*Lancet*, January 23, 1926) has lately made its appearance in Great Britain, and occurs in young children. It has been called erythredema, erythredema polyneuritis, acrodynia, and pink disease. The characteristics are fairly sudden onset in a healthy baby, beginning with irritability, insomnia, and loss of appetite. A miliary rash appears, followed by the development of the characteristic pinkness of the hands, feet, and face, and marked hypotonia of the muscles. Symptoms resembling meningismus appear, and the child becomes intensely miserable with photophobia, gingivitis, and dropping out of the teeth. Death may occur very suddenly as the result of weakness or terminal infection, or the child may make a slow recovery and return to complete health. The rash may continue to appear, sometimes with small pustules, and in most cases desquamation occurs, noticeably at the edges of the pink areas. In severe cases there may be a resemblance to chilblains. The hair becomes dry and wispy. Salivation occurs, and perhaps nasopharyngitis. Ulcers of the mouth are not rare. The pulse is rapid and the blood pressure very high. The blood may show a polymorphonucleosis or a leucocytosis. The urine may show pus (pyelitis?). The progress of the case is (in the author's series of twelve cases) usually favorable, but fatalities may occur.

As to the etiology, this disease occurs in children between one to three years of age. Both sexes are equally affected. Most of the cases occur in the early spring or summer. There is as yet no evidence of cases coming from any one area. There are several theories as to causation; one of the most likely is that it is an infective disease. Nasopharyngitis has been reported and diphtheroid bacilli have been found. The rash is very like a septic condition, and the author has made many attempts to obtain an organism from the pustules, but it is very difficult to find any actual pus, and he only succeeded in obtaining a staphylococcus which was probably a skin infection. Up to the present time cultural examinations of the blood have been negative. Most observers have come to the conclusion that it is not a deficiency disease. The symptoms of salivation, rapid pulse, insomnia, mental depression, and the characteristic pinkness and edema point to disorders of the vegetative nervous system.

The disease may be mistaken for: 1, toxic edema following gastroenteritis; 2, meningitis; 3, multiple neuritis; 4, mental defect; 5, general tuberculosis; 6, congenital syphilis; 7, Raynaud's disease; 8, erythromelalgia; 9, rheumatism with sweat rash; and 10, pellagra. But in none of these is there the characteristic persistent pinkness of the extremities.

The treatment is symptomatic and hygienic. Rest under good hygienic conditions is very important. The diet should be generous. Codliver oil and nux vomica and small doses of arsenic are useful. Thyroid does not do good. For the rash, dusting powders, an ointment of sulphur and phenol ointment (equal parts), and tincture of iodine locally, have been recommended. Internally, calcium lactate is of value. The nasopharynx should be cleared if there is any evidence of infection. Tonsillectomy has been recommended to shorten the duration of the disease. In the photophobia cases tuberculin has given marked benefit.

Two Forms of Dermatitis Due to the Use of Methylated Spirit Externally.—P. B. Mumford (*British Medical Journal*, October 3, 1925) states that the increasing restrictions imposed on the use of alcohol have led to the occurrence of various irritations of the skin in persons who are compelled to use commercial alcohol. Among those hitherto unaffected are surgeons and nurses, who use spirit for the purpose of disinfection, and also hairdressers employing spirit lotions and spirit soaps.

The condition was proved to be due to the alcohol by a process of exclusion of all other factors. When the use of spirit ceased, the dermatitis ceased also. The lesions were of a dry eczematous type and affected particularly the webs of the fingers, the wrists, and the forearms. The lesions were intensely irritable and commenced within twelve hours of exposure; in certain cases fissuring of the skin and superficial bleeding occurred when the condition became severe. Only one of the persons so affected was predisposed to eczema. The exact chemical irritant concerned in these cases was not isolated, but a change of source of supply checked the appearance of the lesions.

The outbreak among the barbers was more extensive and more severe in its results, although two of the cases occurred in men who had had general eczema (from unrecognized causes) elsewhere on the body. Several of the other employees complained of itching, burning, and tingling of the hands after using certain of the preparations.

The socalled dry shampoo contained about fifty per cent. water and forty-eight per cent. alcohol; it also contained a gritty substance, potassium carbonate, and a little coloring matter. It contained no pyridine.

The various frictions contained the following irritants: pyridine, 0.49 per cent. of the total mixture, and twenty-five per cent. of the residue after evaporation on the water bath; also traces of arsenic and aniline coloring matter. It appears that the use of pyridine is very common in spirit, and it is likely that the cause of the trouble lay in the use of spirit containing this denaturant by the manufacturers. Evaporation of the particular friction referred to above left a residue which was largely composed of pyridine and gave rise to irritation of the skin when rubbed in.

Postvaccinal Purpura.—Although there were practically no untoward results observed after almost the entire city of Milwaukee had recently undergone vaccination, Dr. A. B. Schwartz (*American Journal of Diseases of Children*, December, 1925) describes the case of a seven year old boy with purpura occurring after vaccination; no specific relationship, however, could be established. The child made an uneventful recovery.

GENITOURINARY

Tumors of the Testicle.—F. G. Bell (*British Journal of Surgery*, Vol. XIII, No. 50) discusses the seminoma or germinal celled tumor of the testis according to the following plan:

Origin.—It arises from a proliferation of the cells of the seminiferous tubules in precisely the same way as glandular carcinoma of other organs.

Age Incidence.—It declares itself most frequently in the fourth decade.

Rate of Growth—It advances more slowly than teratoid carcinoma.

Structure.—It presents in the main a specific structure which may be definitely related to the seminiferous cells, but is subject to certain variations in type.

Carcinoma or Sarcoma?—Carcinomatous features usually prevail, but it is common to find mixed histological characters in the same tumor. This feature is probably related to the mesothelial origin of the seminal cells and to reversionary tendencies.

Metastases.—Most germinal celled tumors behave like cancer and spread by the lymphatics. Occasional spread by the bloodstream is to be related to sarcomatous characters.

Prostatic Abscess.—L. Herman and J. Carp (*Annals of Surgery*, June, 1925) advocate incision and drainage treatment of this complication since unoperated cases frequently end fatally or in chronic invalidism.

Abscesses of nongonorrheal origin are far more serious as a class than those complicating acute gonorrhea.

The clinical differentiation between intraprostatic and periprostatic abscess is often impossible.

The treatment of choice is perineal extraurethral prostatotomy.

Diversion of the urinary stream by means of an external urethrotomy is advisable in cases complicated by large periprostatic collection and especially in chronic cases.

Leucocytosis is one of the most important diagnostic signs.

Acute Urethritis in the Male.—D. A. Sinclair (*International Journal of Medicine and Surgery*, Vol. XXXVIII, No. 12) says that in a certain number of cases of specific urethritis, seen within the first few days of the onset, where the infection was limited to the anterior portion of the urethra, I have tried out neutral acriflavine, as a hand injection, four times a day, with gratifying results in a few cases, succeeding in completely checking the disease within two weeks; but in the majority of instances I was disappointed, for the infection persisted and invaded the posterior urethra. Nevertheless, this drug is worthy of at least a week's trial, especially if the disease is seen within the first few days after infection. If, in our judgment, the result is not promising, argyrol or protargol is substituted and, combined with this, daily irrigations of potassium per-

manganate to the anterior urethra. Mercurochrome has been tried by me in the same manner, but was found to be too irritating, making matters worse, and so I have discontinued its use altogether.

For acute epididymitis the patient should be confined to his bed, and the scrotum supported by means of the so-called Bellevue bridge, or by a small soft pillow between the legs and against the perineum. Hot flaxseed poultices, about seven inches in diameter and two inches thick, should be applied every hour while the patient is awake, and he should be warned against using them too hot, otherwise blistering of the parts will follow. An ice bag, partly filled with finely chopped ice, gives relief, but is not as efficient as the poultices. The use of gonorrheal vaccines may be of help and is recommended for a trial. In unusually mild cases of acute epididymitis, the process is limited to the globus minor, but in the greater number the body and head of the epididymis partake in the inflammation. The testicle is rarely, if ever, involved, but there is always an exudation of serum into the cavity of the tunica vaginalis, producing symptomatic hydrocele. Under rest in bed and appropriate treatment the acute inflammation usually subsides in from one to two weeks, leaving a thickened epididymis, for weeks or perhaps months afterward, before complete resolution may be said to have taken place. Resumption of local treatment to the urethra or prostate should be cautiously undertaken, lest a relapse be precipitated. In the severer or fulminating type of epididymitis, attended by extraordinary pain and prostration and rebellious to the antiphlogistic measures employed, or in acute or sub acute relapses, surgical intervention is indicated, and the pus found in the globus minor evacuated. This procedure always brings quick relief of the pain and shortens what would otherwise be a tedious, long drawn out convalescence.

Ureteral Strictures, Kinks, and Abnormal Inserts.—D. Eisendrath (*Surgery, Gynecology and Obstetrics,* Vol. XLI, No. 5) maintains that the "hang" test, after the manner of Hunner, is not above dispute. If one watches, through an operating cystocope, the wax bulb during its withdrawal, one will see that the "hang" is obtained at a point where the ureter is normally very narrow, i. e., at the vesical outlet. Again the angle formed by the justavesical and intraparietal portions of the ureter will lead us astray unless we bear it in mind in withdrawing the bulb. The use of solid bougies of varying sizes in determining the caliber of the different levels of the ureter is more accurate than any other method. It is therefore open to question whether the examination for the presence of ureteral strictures should not be limited to the ureteral bougie, plus ureteropyelography. This latter method should be carried out by first filling the renal pelvis and then making one exposure. A little more of the opaque medium should then be injected until the catheter has been completely withdrawn, and then a second film exposed. We feel fairly confident that when increased pressure and more of the opaque medium are employed the normal ureter will not dilate enough to result in widening the ureteral shadow. We are, however, continuing to experiment on this question.

Ureteral stricture occurs far more frequently than was formerly thought to be the case. During the past three years we have found in patients of all ages strictures when least suspected, by keeping their possible presence in mind in cases of abdominal pain of obscure origin, in recurrent ureteral colics or calculus formation, in hematuria, and in persistent pyelitis. In these cases the improvement obtained after dilatation combined with pelvic lavage ought to convince anyone with an open mind that he who overlooks the occurrence of ureteral stricture is neglectful of his duty toward his patient.

As regards ureteral kinks one should not draw the deduction that when a kink is seen in the ureteropyelogram it is necessarily responsible for all of the symptoms. If, however, we have evidences of renal infection clinically, and these are confirmed by the urological study of the case, it is justifiable to state that the kink is responsible for the obstruction to the escape of the pelvic contents.

Under normal conditions the ureter arises from the most dependent portion of the renal pelvis. The advantage of this form of ureteropelvic junction from the standpoint of drainage is self evident. Although the renal pelvis is simply an expansion of the cephalic end of the embryonic ureter, a faulty development may take place so that the ureter joins the pelvis at a higher point. This anomaly has been known for years, and a fairly large number of plastic operations have been done to correct it.

My only object in bringing this anomaly before you is to direct attention to the possibility of recognizing it before operation through the aid of ureteropyelography. In three recent cases the chief complaint was recurrent pain over the kidney or one of the upper abdominal quadrants.

In all of the ureteropyelograms one can observe that the ureter passes either in front of, or behind, the lowermost point of the renal pelvis, before entering the latter. The knowledge of the existence of such an anomaly is not only of great value from a diagnostic standpoint, but also from that of treatment. Some form of plastic operation should be advised at an early stage, before pathological changes due to infection endanger the success of such a procedure.

Chronic Anterior Gonorrheal Urethritis.—F. Bierhoff (*International Journal of Medicine and Surgery,* Vol. XXXVIII, No. 12) advises the use of the endoscope where treatment by dilatation has failed to destroy all the gonococci, in order to locate the individual foci and to destroy them.

For this purpose it is advisable to employ a tube of at least twenty-five French calibre, since smaller tubes do not permit of easy manipulation of the necessary instruments. If necessary, a meatotomy should be done. Through the endoscopic tube the diseased glands may be slit with the endoscopic knife, after which the dilatations may be resumed or we may resort to their electrolytic destruction. My personal preference is for the latter procedure, which is done as follows: Under a local anesthetic, preferably novocain, in one-half to one per cent. solution—after preliminary disinfection of the urethra—the endoscope is inserted, and the diseased glands and lacunas located. Those which are most diseased should be attacked first.

A moist sponge electrode, attached to the *positive* pole of the electric source, is applied to the thigh of the patient, while the urethral electrode is attached to the *negative.* The point of the urethral electrode is inserted into the mouth of the affected gland, and gently pushed in until it meets with resistance. Force should never be used. The contact is now made, and a current of three milliamperes allowed to flow. If the current is passing properly, small gas-bubbles will be seen to appear at the mouth of the gland, continuing as long as the current is on. It is customary to apply the current only for about one and one-half to two minutes for each gland, and to treat from four to six glands at a sitting. If a stronger current is applied, there is apt to be a painful, though harmless shock experienced by the patient on making and breaking the current, and the reaction following the applications may be severe where the stronger current is used, or where more glands are treated at one sitting. The sessions should be at from five to seven day intervals.

When the current has been properly employed, there will be found, upon removal of the electrode and wiping away of the bead of froth, at the point of electrolysis, a deeply reddened and infiltrated zone, surrounding the gland which has been thus treated. On subsequent examinations, the discoloration is darker in color, but rapidly disappears. It is my custom to treat every gland which shows inflammatory changes, even though a distinct discharge of pus from it may not be discernible. Usually several applications are needed, glands being repeatedly treated until they are dry, after the disappearance of the zone of reaction.

MALIGNANT GROWTHS

Some Points in the Diagnosis and Treatment of Tuberculosis and Cancer of the Larynx.—James Dundas-Grant (*Clinical Journal,* December 9, 1925) concludes his long paper, begun in the October 7th issue of this journal, by emphasizing the following points:

1. Actual cure may take place in a large proportion of cases of tuberculosis in the slighter forms, and even in some very advanced cases, persevering treatment may result in a subsidence and even disappearance of the lesions. Among the remedial agents comes first and foremost the maintenance of silence. The inhalation of antiseptic vapours and solutions is a valuable subsidiary aid at the disposal of every practitioner. The cirrhosing action of the galvanocautery point cannot be overrated as long as it is not overdone, but can only be practised by the expert. For the relief of pain the practitioner has at his disposal a most precious resource in Leduc's tube and the anæsthetic powders used with it,

while the more delicate operation of injecting alcohol into the superior laryngeal nerve is very effective both in tuberculosis and cancer of the larynx. Difficulty in drinking due to regurgitation is generally overcome by the use of Wolfenden's method, and occasionally by removal of a mass of tissue preventing the closure of the glottis.

2. The absolute necessity for early diagnosis, especially in view of the brilliant possibilities in intrinsic and, to a lesser degree, in extrinsic cancer of the larynx if timely operation is practised. As an outcome, the more extensive use of the method of removal of a portion of tissue for microscopical examination in view of the difficulty of diagnosis by inspection in the early stages, even in the hands of acknowledged experts.

3. Thyrotomy for circumscribed intrinsic carcinoma is almost invariably successful and that even if from omission of biopsy it happens to be performed in a case of tuberculosis so localized as to simulate carcinoma, it does not necessarily destroy the patient's chances.

4. Total laryngectomy, though a serious and mutilating operation, is now a thoroughly practicable one, which tends to become still more so in view of the development it is at present undergoing.

5. Though radiologists at present are agreed that if the disease can be removed by surgery this should be done forthwith, the time may come when the scope of application and, above all, the dose of the rays are so accurately defined that radiotherapy may precede other methods.

Cancer of the Lower Lip.—W. Herbert McGuffin (*Canadian Medical Association Journal,* October, 1925) submits these rules as a summary of his paper. 1. Examine carefully such benign conditions of the lower lip as warts, cracked lips and cold sores, keratoses and leucoplakia, which are all forerunners of cancer.

2. Classify the epitheliomata into superficial, papillary, deeply infiltrating, and glandular types.

3. First type is a radium case.

4. Second type should be treated by radium and x rays, then surgery, and finally by radium and x rays.

5. Third type is a radium and x ray case.

6. Don't forget the hygienic and supporting treatment: such as, cleanliness and avoidance of all sources of irritation in the treated area; fresh air, sunshine and rest; suitable diet, and alleviation of coexisting symptoms.

7. Follow up the progress of your cases.

ENDOCRINOLOGY

Anuric Diabetic Coma.—A. Clarke Begg (*Lancet,* July 11, 1925) recognizes two distinct types of diabetic coma: 1, the ordinary type associated with acidosis, which, as a rule, recovers with insulin treatment; and 2, the type with little or no acidosis (the socalled postoperative type), in which the patient dies in spite of the most energetic treatment.

The points common to both varieties of coma are: 1, drowsiness going on to coma; 2, vomiting (usually) and constipation; 3, lowered tension of eyeballs; 4, raised blood sugar; 5, glycosuria; 6, tendency to heart failure.

The differences between the two types are:

Ordinary diabetic coma with acidosis.—1, Blood: blood sugar moderately high; blood urea about normal. 2, Urine: good quantity and soon becomes increased with treatment; much acetone and diacetic acid; no albumin (usually). 3, Clinical: coma usually deep some time before death; air hunger marked; odor of newmown hay in breath. 4, Prognosis: insulin treatment usually cures.

Diabetic coma with absent or slight acidosis.—1, Blood: blood sugar very high; blood urea very high. 2, Urine: usually small quantity going on to complete anuria; little or no acetone or diacetic acid; some albumin. 3, Clinical: coma often not deep till just before death; air hunger absent or slight; no odor of newmown hay in breath. 4, Prognosis: Usually fatal from anuria.

Whether this type of diabetic coma without acidosis is a distinct entity is doubtful, as some of the cases begin with the typical signs of ordinary diabetic coma, and it is only when the acidosis has cleared up under treatment, without corresponding clinical improvement, that they show themselves to be of the definite anuric type described above. Be that as it may, it is certain that as regards symptoms, physical signs, course and prognosis, it is a distinct clinical type and that the immediate cause of death is suppression of urine.

The condition might be called diabetic coma of the renal type, but until further knowledge is gained the most suitable name would appear to be "anuric diabetic coma." This has the advantage of emphasizing the outstanding symptoms of the disease and the one for the relief of which all our energies have to be directed.

Rapid Alterations in the Blood Sugar Level of Rabbits as Result of Intravenous Injections of Killed Bacteria of Various Types.—Isolde T. Zeckwer and Helen Goodell (*Journal of Experimental Medicine,* July, 1925) produced a rapid rise in the blood sugar level of rabbits by intravenous injection of killed Bacillus proteus, Bacillus coli, and Bacillus paratyphosus B. In a few hours time this returned to nearly the previous level. The results with Bacillus enteritides and Bacillus paratyphosus B are in accord with the report of Menten and Manning. A less pronounced rise in blood sugar was produced by these two organisms than by those of the first group.

Hyperthyroidism.—N. B. Foster (*American Journal of Surgery,* Vol. XXXIX, No. 12) asserts that while iodine is definitely useful, its employment in each case is an experiment. The duration of its effect is not yet known, nor has it any effect in cases of toxic adenoma.

As to surgery the cases of toxic adenoma occurring in patients in middle life admit of no debate. If the thyroid tumor is not removed the patients succumb to cardiac disorders induced by thyrotoxicosis or to thyrotoxicosis purely.

While it seems to me debatable whether the average patient with exophthalmic goitre is in a better state of health a year after removal of the thyroid than he would have been at the same time had no operation been done but all the other measures in treatment were just as carefully carried out, I do not think that his best insurance against a return of the thyrotoxic state five or ten years hence is in having had the thyroid removed.

Probably only the minority of the patients who have had exophthalmic goitre ever attain normal robust health. While many attain sufficient health to lead useful lives there is quite commonly a residue of nervous symptoms, emotional instability, or low vascular tone which compels the individual to lead a life more protected than is consistent with the term "cured." It has been claimed that this is the constitutional make-up on which exophthalmic goitre as a disease is engrafted, that only those of this constitution are susceptible and that after successful treatment the patient again is restored to a state normal for him but still abnormal. This seems to me unsatisfactory in that it evades the essential problem of etiology.

Surgery in Diabetics.—H. Roth (*American Journal of Surgery,* Vol. XXXIX, No. 12) reports on twenty cases, of which only two of the total number succumbed. His success he attributes to the various measures employed to reduce the existing hyperglycemia and acidosis to a point of comparative safety, which measures he describes as follows: If the surgical complication of the diabetes was such that prompt surgical intervention was imperative to save life, no time was lost in delaying operation for too much laboratory investigation or for thorough medical preparation of the patient. Occasionally it may be permissible and advisable to carefully administer insulin and glucose before and even during a prolonged operation, bearing in mind the danger of rendering a patient rapidly and entirely sugar free. To control acidosis a sufficiently amount of water was administered either by mouth, rectum, hypodermatically or intravenously. This was essential, especially in patients with fever or in those who had been vomiting or were unable to retain nourishment for some time before the operation or in those who were likely to vomit after anesthesia. Next in importance was the administration of an adequate quantity of carbohydrates, proteins, and fat. Rectal injections of a ten per cent. solution of glucose were frequently employed and orange juice was given to patients who could take fluids by mouth. The dosage of insulin given depended upon the degree of hyperglycemia and acidosis and upon the amount of sugar and diacetic acid in the urine. The latter was examined at short intervals, usually every two or three hours. After operation the quantity of insulin to be given was gauged to a great

extent in the same way. In several cases the use of insulin was discontinued entirely, because the patients were found doing well on the prescribed diet. The patients requiring operations for some chronic condition, such as hernia, gallbladder, pancreatic disease, or hypertrophied prostate, etc., were prepared for several days before operation by proper dietary measures and the administration of insulin in sufficient dosage to reduce the existing hyperglycemia and acidosis.

The selection and administration of the necessary anesthetic received careful consideration. Novocain, used locally, was considered the safest anesthetic, providing that the operation was such that it could be completed in every detail with the aid of this particular kind of anesthesia. Novocain may also be used for spinal, paravertebral, sacral and parasacral anesthesia. As a general anesthesia nitrous oxide and oxygen is undoubtedly the safest combination for diabetic patients, as it is the least likely to cause postoperative acidosis.

Knowing that the tissues of diabetics are very susceptible to pyogenic infections, that the lowered resistance of their tissues favors the rapid spread of an infection, and that diabetes is more difficult to control when an infection is present, all infections were promptly drained and treated according to accepted surgical principles. After such drainage the fever and acidosis usually subside and the diabetes becomes more amenable to antidiabetic treatment.

The Hypophysial Adenomata.—N. M. Dott and P. Bailey (*British Journal of Surgery,* Vol. XIII, No. 50) present a detailed study of cases of this complication with a prefatory note by Harvey Cushing. They state in conclusion:

1. A clinico pathological study of one hundred and sixty-two examples of pituitary adenomata shows that three fairly definite types of tumor can be histologically recognized and that they represent more or less definite clinical syndromes.

2. The syndrome of acromegaly corresponds with the chromophil adenoma, that of hypopituitarism with a chromophobe adenoma, and the mixed syndrome with a mixed type of adenoma.

3. Though our knowledge of the physiological action of the pars distalis is in its infancy, it may be asserted not only that it exerts an influence on growth, but that the eosinophilic cells are the ones chiefly concerned. In the absence of an increase in the number of these cells, evidences of overgrowth of one sort or another have not been found to occur.

4. We have as yet no knowledge of the biochemical influences which underlie the formation of these adenomata, and can only draw analogies from the better known lesions of the thyroid in arriving at our interpretations of them.

5. The treatment of these lesions is therefore still at the primitive stage in which a radical operative measure, rather than some simpler agent, is called upon to relieve the effects of local pressure on important neighboring structures.

Effect of a Parathyroid Hormone on Normal Animals.—J. B. Collip, E. P. Clark, and J. W. Scott (*Journal of Biological Chemistry,* March, 1925) describes the effect of the subcutaneous and oral administrations of a parathyroid hormone to normal dogs. A potent extract, administered subcutaneously, will cause a rise in the level of blood serum calcium. Successive injections produce a profound hypercalcemia, which, when long maintained, may result in death.

Demonstration of the Hyperadrenalinemia Induced by Experimental Cerebral Embolism.—A. Tournade (*Bulletin de l'Académie de Médicine,* October 6, 1925) alludes to certain experiments of Roger in which powdered lycopodium or an alcoholic solution of betanaphthol was injected into the carotid artery in animals to produce cerebral embolism. Roger had concluded that the rise of bloodpressure witnessed as a result of the embolism was due to the adrenal secretion. The rise of pressure was much more pronounced and prolonged in normal animals than in animals previously subjected to bilateral adrenalectomy. The author has confirmed Roger's conclusion in experiments involving union of two dogs by venous adrenaljugular anastomosis. Dog A, receiving the blood, has already been subjected to bilateral adrenalectomy, while from dog B, the donor, only the right adrenal has been removed, and the blood from the left adrenal passes over to dog A. Upon injection of two mils of alcoholic betanaphthol solution into the central end of one of the carotids of dog B, both animals show a rise of bloodpressure. This, in dog B, is evidently purely nervous in origin, while in the transfused dog A it is solely due to adrenalin. Another proof of the agency of adrenalin in the rise of pressure in dog A is that the spleen contracts vigorously along with the rise of pressure. Aside from the element of shock presumably resulting from cerebral embolism, such embolism exposes the bulbo-excephalic centres to an immediate anemia, soon followed by asphyxia. In earlier experiments the author had already demonstrated the ability of cerebral anemia and asphyxia to stimulate adrenal secretion.

Studies on Experimental Hypophysectomy.—I. Effect on the Maintenance of Life.—Walter E. Dandy and Frederick Leet Reichert (*Bulletin of the Johns Hopkins Hospital,* July, 1925) directed their efforts toward the development of a method as free from operative complications, trauma and hemorrhage as possible. The temporal intracranial route originally devised by Horsley was chosen, and only a unilateral bone opening was made. The operative technic is described in full. This operation is satisfactory for dogs older than six months, but for younger puppies the brain shrinking by the method of Weed and McKibben by intravenous injection of concentrated sodium chloride solution is done preliminary to the hypophysectomy. Of thirty-one adult dogs, five died soon after operation from hemorrhage and cerebral trauma; seven died in the country where they were sent for the summer, and distemper caused ten deaths, ranging from eight days to one year postoperative. In seven of the series the base of the brain was sectioned serially and studied for microscopic remnants of the anterior lobe, with negative results. The duration of life in these seven histologically proved total extirpations was thirteen, twenty-two, twenty-seven, sixty-nine, ninety, one hundred and four, and one hundred and thirty-eight days. In the young puppies in which Weed's hypertonic salt solution was used, the operative procedure was safe, all deaths following soon after operation being explainable as the result of trauma, hemorrhage and pneumonia, and deaths appearing later were explained on well recognized pathological grounds. No evidence therefore was found to support, and every evidence to refute, the assumption that the hypophysis is essential to life, or that the group of symptoms which have been described by others as preceding death in hypophysectomized animals are of hypophyseal origin.

Insulin and the Leucocyte Count.—G. Török (*Wiener klinische Wochenschrift,* October 29, 1925) found that after a subcutaneous injection of insulin, the number of leucocytes at first is diminished and then gradually rises. In man the rise is usually moderate and of short duration. The reduction in the number of leucocytes does not run parallel with the hypoglycemia because the rise in the count appears earlier than the recovery from the hypoglycemia. No relationship could be established between the changed leucocyte count and the thickness of the blood in man, as the leucocytes show a diminution in number even when the refraction of the serum revealed thickening of the blood. Inasmuch as the blood sugar content was low during the rising stage of the leucocyte count, it is not probable that such a relationship between the change in the leucocyte count resulting from insulin and the blood sugar content exists as has been found by Csépai and Weisz between the blood sugar content and the cardiovascular effect of insulin.

Influence of Abrupt Variations in Acid Concentration on the Thymus and Lymphopoietic Organs.—According to A. P. Dustin (*Revue Française d'Endocrinologie,* February, 1926, vol. 4), the extreme sensitiveness of the thymus and lymphopoietic organs to suspended or insufficient alimentation is a well known fact. On the other hand, during fasting a marked hyperacidosis is known to affect the organism. Experimental injection of acid causes extensive pycnotic disintegration of the smaller cells of the thymic cortex and to a less degree of the lymph cells in the germinal nuclei of the spleen, lymph glands, and Peyer's patches. This effect is selective and is not accompanied by passive destruction or by essential disturbance of other tissues. It is certain, then, that there exists in the organism a class of cells presenting acute sensitiveness, according to their nature, the state of their development, and perhaps also their histological relations, to reactive variations in their surroundings.

Medicolegal Notes.

LIABILITY OF PRIVATE HOSPITAL—PHYSICIAN NOT LIABLE FOR ERROR OF JUDGMENT

The West Virginia Supreme Court of Appeals holds, Vaughn vs. Memorial Hospital, 130 S. E. 481, that a hospital conducted for private gain is liable to its patient for injuries sustained by him in consequence of incompetence or negligence of a physician treating him at its instance under a contract to furnish him proper treatment. The purely private character of the defendant hospital was practically admitted. The plaintiff and defendant were brought together through the agency of the former's employer. In the hospital the plaintiff received the surgical and medical care to which he was entitled under the rules and regulations of the state compensation commission, the expense of such treatment and care to be paid out of the Workmen's Compensation Fund. The application to the Commission for payment of the medical, surgical and hospital treatment afforded plaintiff was rendered in the defendant's name. It included an item for an operation on the plaintiff's foot by doctors who were managers of the hospital. The X-ray machine used in the hospital for examination of the plaintiff's injury was the property of the institution. Under these circumstances it was held that the defendant could not absolve itself from the obligation it owed to the plaintiff patient to furnish him proper treatment on the claim that the physicians who treated him at his instance were independent contractors.

A verdict for the plaintiff was held to have been properly set aside and a new trial awarded to be had in accordance with the following principles announced by the Supreme Court. The Court says that it may be said to be the generally accepted doctrine that a physician is not required to exercise the highest degree of care or skill and deligence possible in the treatment of an injury or disease unless he has by special contract agreed to do so. "In the absence of such special contract, he is only required to exercise such reasonable and ordinary skill and diligence as are ordinarly possessed and exercised by the average of the members of the profession in good standing in similar localities and in the same general line of practice; regard being had to the state of medical science at the time." This general rule does not make the physician in any sense a warrantor or insurer of the success of his treatment in the absence of a special contract to that effect. An instruction was held properly refused which would have told the jury in effect that the physician was responsible for an error of judgment, without qualification, in the treatment of the plaintiff. If the physician possesses ordinary skill and exercises ordinary care in applying it, he is not responsible for mistakes of judgment, unless such error of judgment is so gross as to be inconsistent with that degree of skill which it is the duty of a physician to possess.

At the trial the plaintiff relied almost entirely upon the result which he claimed followed the treatment—that, by reason of the broken bones not being properly set, the bones at the point of the injury decayed and produced pus. Upon this question the evidence was conflicting. The bones taken from the foot were introduced. It was held that the trial court properly refused to permit them to go in evidence to the jury for lack of being properly identified. The physician who took them from the foot was not introduced as a witness, nor was his deposition taken. His absence was not accounted for. It was held that if the testimony of this witness was material to the plaintiff's case, and the plaintiff wished to avoid the effect of the legal presumption that, if he had testified, his testimony would have been adverse to him, he should show proper diligence to have him present as a witness or take his deposition.

MEMORANDUM OF LOST X RAY PHOTOGRAPHY MAY AID RECOLLECTION OF WITNESS

The St. Louis (Mo.) Court of Appeals holds, Schroeder v. Wells, 277 S. W. 578, that the testimony of a physician as to the injuries of a plaintiff in a personal enjury action, based on a carbon copy of a memorandum made by him of an x ray photograph which he took of plaintiff's lumbar region, which photograph was lost, was competent although he stated that after having examined the memorandum he had "no independent recollection of the result of the photograph other than what was contained in the memorandum," where his further testimony on cross-examination showed that he then remembered that when he made the memorandum of what the photograph showed he knew it to be correct.

EFFECT OF STRYCHNINE AND PROOF OF FATAL DOSE

On appeal from a conviction of murder by administering strychnine, it appeared that at the trial the prosecution called all eyewitnesses of the death, who testified that it was peaceful and without convulsions. The jury evidently found that strychnine was given in oatmeal or coffee at least two hours before death, caused death, and, notwithstanding the testimony of all eyewitnesses, that death was preceded by convulsions. A fatal does of strychnine, the Michigan Supreme Court said, if it does not cause immediate death, produces severe convulsions ending in death. If the poison found in the organs of the body was given about two hours before death, the doctors agreed there must of necessity have been convulsions. This uncontroverted medical evidence was directly opposed to the testimony of the eyewitnesses, and presented an issue of fact for the jury. The medical evidence was also to the effect that the accepted minimum fatal dose of strychnine is about one half grain, and may be slightly less. It is quick in action, goes to all parts of the body, because it is taken up from the stomach and intestines and carried through the blood stream everywhere the blood circulates, and a fatal dose causes death from almost immediately to three hours, and if an analysis of a well sampled one half of the stomach of a dead body, one half of the liver, and one half of the kidneys, disclosed .26 of a grain of strychnine, there would be sufficient in the system to cause death, for there would be approximately the same amount in the other half of the organs mentioned, and, if those organs contained .52 of a grain of strychnine, it would of necessity have produced convulsions, and was sufficient to have caused death.

A chemist and toxicologist made a chemical analysis of a well sampled half of the stomach, liver and kidneys, and found therein .26 of a grain of strychnine, and, over objection, was permitted to say there was, of necessity, an equal amount in the unexamined portion of the same organs. His qualification to give such conclusion was attacked. The appellate court held that the qualified medical testimony relative to the nature of strychnine and the method of its operation in the human body through the circulatory system rendered his conclusion true beyond question. His testimony was supplemented by uncontroverted competent medical testimony showing the correctness of his statement, and, without passing upon the question of his qualifications, the court discovered no harm done the defendant by his statement of a fact conclusively established by medical expert testimony. The record was held fully to support the finding that the death was caused by strychnine.

Allergy*

E. M. ROBINSON, M.D.
Brooklyn, N. Y.

Allergy, one of the most interesting and important phenomena in medicine today, was brought to light quite recently. It is only about twenty years since anaphylaxis ceased to be a mere laboratory curiosity and its reactions in animals have been studied and reported by such men as Richet, Arthus, Theobald Smith, Rosenau, Zinsser and others. As far as allergy is responsible for human ailments its studies are even of a more recent date. It is only about ten years since such men as Doerr, Schloss, Walker, Coca and Cooke have reported their investigations in the diagnosis and treatment of human allergy.

It is no wonder, therefore, that the medical profession at large knows little about anaphylaxis, although W. W. Duke states (1) that as high as fifteen per cent. of humanity suffer from allergic manifestations in one form or another. Coca, who is more conservative, estimates the allergic sufferers to be about eight per cent.

The phenomenon of anaphylaxis is without a specific name even yet. Richet, who was the first to describe this phenomenon, called it anaphylaxis, which is from the Greek and means "without protection," in contradistinction to prophylaxis. Zinsser also uses the name anaphylaxis. Von Pirquet was the first to call it allergy which means "all-alter ergy-energy—altered energy," or altered reaction. Vaughan calls it protein sensitization and Coca calls it specific hypersensitiveness and also atopy.

WHAT IS ANAPHYLAXIS?

If you take four guineapigs and inject two of them with a certain protein—it may be egg, milk or horse serum—the two injected guineapigs will show a slight reaction; they will become drowsy and will have hemoglobinuria. This will disappear in a day or two, and they will become as well as the other two animals that were not injected. Now if, let us say, in about fifteen days you take the same kind of protein and inject all four guineapigs, an interesting thing will take place. The two animals injected for the first time will show the same symptoms as the two that were injected fifteen days previously, that is, drowsiness and hemoglobinuria; while the two that were injected the second time will show an entirely different picture. They will become violently ill and may die in a few hours or even in a few minutes, and this altered reaction to a second injection of protein we call anaphylaxis. Why and where this reaction takes place we shall discuss later.

The first to mention anything about anaphylaxis was Magendy, the famous French physician. In his lectures, published in 1839, he states that dogs which have been repeatedly injected with egg albumin die suddenly.

Flexner, in 1894, gave a clear statement of the phenomenon. In describing certain experiments he said, "Animals that had withstood one dose of dog serum succumb to a second dose given after the elapse of some days or weeks."

But it was Richet whose investigations in collaboration first with Harcourt and then with Portier during the period of 1898-1902, marked the beginning of modern understanding of the anaphylactic phenomenon. He was the first to recognize the distinct dependence of the hypersusceptible condition upon a preceding inoculation with the same substance, and that a definite incubation time must elapse after the first injection before susceptibility is developed.

In 1904, Theobald Smith communicated to Ehrlich that guineapigs inoculated with horse serum for the purpose of standardizing antitoxin acquired hypersusceptibility to subsequent inoculations given several weeks later.

In 1905, Otto, of the Frankfort Institute of Experimental Therapy, described this condition as the Theobald Smith phenomenon, and showed that it was entirely independent of the toxin and antitoxin it contained but could be produced with horse serum alone.

At this time a number of investigators took up the study of anaphylaxis and chief among them were Rosenau and Anderson of the Hygienic Laboratory of the United States Public Health Service. These American scientists attacked the problem with the primary purpose of throwing light upon the occasional cases of sudden death following the injection of diphtheria antitoxin in human beings. As a result of their classical investigations and the intensive experimental work of such men as Otto, Doerr, Wells, von Pirquet, Dale and of some of the more modern men such as Zinsser, Longcope and Coca, the following facts are known to us today.

A single injection of horse serum into guineapigs, harmless in itself, renders these animals hypersus-

ceptible to a subsequent injection given after a definite interval or incubation time. This incubation period is about twelve to fifteen days, a second injection after this time is usually fatal. The reaction is extremely delicate. Rosenau and Anderson succeeded in sensitizing a guineapig in one case, with one one millionth of a c. c. Just think of it, one one millionth of a c. c., which is about one one hundred thousandth of a drop.

The reaction is specific; that is, horse serum sensitizes to horse serum only. Rosenau and Anderson have shown by their experiments that a guineapig can be rendered separately sensitive at one and the same time to blood serum, egg white, and milk, or to a combination of other proteins reacting specifically to each on a second injection.

Another characteristic thing about anaphylactic specificity is that there is more organ specificity than specificity of species. Kraus, Doerr and Sohma showed that animals sensitized with protein from the crystalline lens, let us say, of the dog will react to the protein from the crystalline lens of all other animals but will not react to dog serum. This shows that the protein of the crystalline lens contains a certain characteristic variety of protein peculiar to this kind of organ throughout the different animal species but not common to other tissues and organs of the same animal.

WHAT CAUSES THE ANAPHYLACTIC SHOCK?

The anaphylactic shock is due to the union of the antigen and antibody. An antigen is a substance that upon entering the animal circulation produces new substances which are called antibodies. An antibody is a substance which is brought to existence by the entrance of an antigen into the blood circulation of an animal. For example, we take diphtheria toxin and antitoxin. In diphtheria the toxin is the antigen and the antitoxin is the antibody. In the circulation of a healthy child there is neither antigen toxin or antibody antitoxin, but when the Klebs-Loefler bacilli, lodged in the throat or elsewhere, begin to produce toxin and the toxin enters the circulation it becomes an antigen and causes the production of antitoxin antibodies, a substance which did not exist in the circulation before.

In anaphylaxis the protein is the antigen, so that when we inject the protein into the circulation of the animal for the first time it produces antibodies, and when we inject the second time the antigen protein unites with the antibodies which were produced by the first or sensitizing injection. But while in diphtheria the antitoxin by its union with the toxin neutralizes the toxin and destroys the deleterious and poisonous effect of the toxin on the body cells, in anaphylaxis an altogether different thing happens. By the union of the antigen with the antibodies a new substance is formed, a very poisonous one, which is called anaphylatoxin, and this substance is responsible for the anaphylactic deaths and other anaphylactic reactions.

Now that we know about antigen and antibody in anaphylaxis we can speak about other anaphylactic phenomena.

When we inject an animal with protein, and after a few weeks inject him again with the same protein and get an anaphylactic reaction, we speak of it as active anaphylaxis. There is also such a thing as passive anaphylaxis. When we take the blood of a rabbit that has been sensitized with horse serum and inject it into a dog, this injected dog will also become sensitive to horse serum and will give an anaphylactic reaction with the first injection of horse serum; because by injecting into the dog the blood of the sensitized rabbit you have injected antibodies which are specific of horse serum antigen. This is passive anaphylaxis. In the same way if you sensitize a pregnant female to egg white, the offspring will be sensitive to egg white. This is not a true heredity but it simply means that the antibodies from the mother's circulation have entered into the circulation of the offspring.

Where does the union of the antigen and antibody take place? Earlier views favored the theory that it took place in the blood circulation. Now it is believed by most observers that the antigen antibody union takes place in the tissue cells and the reasons for this view are as follows:

1. In passive anaphylaxis (as you will remember) we do not inject the animal which we wish to sensitize with protein which would after an incubation period of at least twelve days produce antibodies. (This would be active anaphylaxis.) In passive anaphylaxis, our first injection is a serum which contains formed antibodies. Now, then, in this case we should be able to bring on an anaphylactic shock by immediately injecting the antigen after we inject the antibody containing serum. However, this is not the case. Even when both serum and antigen are injected intravenously there must be an interval of at least four hours between the injection of the antibody and the injection of the antigen, otherwise there will be no anaphylactic reaction. This time, it is now believed by many, to be necessary for the antibodies to attach themselves to the tissue cells.

2. The transfusion experiment. Manwaring was one of the first to do this experiment. He bled a sensitized dog extensively and reinfused him with the blood of a normal dog until there had been an almost complete replacement of blood. He found that the sensitized animal in spite of the replacement of his blood still remained sensitive.

SYMPTOMS

Symptoms of anaphylaxis vary in different species of animals and also vary according to the degree of sensitiveness of the animal, the dose of antigen administered, and the mode of administration. Symptoms may be so mild that one hardly notices them, or, on the other hand, they may be so severe as to terminate fatally within a few minutes.

If a properly sensitized guineapig receives a second injection of an antigen a characteristic train of symptoms ensues. There is usually a short preliminary period lasting either a fraction of a minute or several minutes during which the pig appears normal. At the end of this time the animal will grow restless. It may sneeze and occasionally emit short coughing sounds. At the same time an increased rapidity of respiration is noticeable. In light cases the animal may remain in this condition for some time then gradually slow recovery may set in, with complete return to normal in from thirty minutes to several hours. In more severe cases these preliminary stages are rapidly followed by great apparent weakness. The animal falls to the side, the legs and trunk muscles twitch irregularly and the respiration becomes

slow and shallow; the thorax never entirely contracts, but remains in a more or less expanded condition. The excursions of the lung itself seems to grow more and more shallow in spite of apparently strong inspiratory efforts, the volume of the thorax and lung remaining in the expanded condition. At this stage evidences of motor nerve irritation may appear, in that the animal may arise and attempt to run. More often, however, in this phase general convulsions set in, often several times repeated, and in these the animal usually dies.

If such an animal is immediately autopsied a characteristic condition is found. The lungs are distended and completely fill the thorax. They are usually pale and bloodless and do not collapse when the pleuræ are opened, due to a tetanic contraction of the small bronchials which practically occlude the air passages.

The symptoms of acute anaphylactic shock in the rabbit are different from those of the guineapig, in that in the rabbit there is no suggestion of the outstanding symptom of dyspnea that characterizes acute anaphylactic shock in the guineapig. After an interval of about two minutes following the second protein injection, the sensitized rabbit may run aimlessly or may fall over from extreme weakness, and after a few short gasps the animal dies with the eyes in exophthalmos.

Autopsy reveals the lungs in collapsed condition and capable of normal inflation and deflation. Coca tried perfusion of the pulmonary circulation through a cannula in the pulmonary artery and found the vessels completely obstructed and resisting a pressure of more than ninety c. c. of saline, while a pressure of ten c. c. will perfuse the normal pulmonary vascular system of the rabbit. And he justly concludes that death in the anaphylactic rabbit is probably due to a tonic spasm of the muscular coat of the pulmonary arterials.

Manwaring proved that the site of the anaphylactic reaction in the dog is in the liver. The characteristic pathology of acute anaphylactic shock in this animal consists of a tremendous congestion of the liver with a secondary stasis of the portal circulation. The effect of this is the collection of almost all of the animal's blood in the abdomen with a corresponding ischemia of the central nervous system and of the thoracic viscera. The cause of rapidly falling blood pressure which was one of the earliest anaphylactic symptoms noted in these animals can readily be understood because, as Coca remarks in his *Essentials of Immunology,* "in acute anaphylactic shock the dog bleeds into its own liver and abdominal veins."

The symptoms of anaphylactic shock in the dog are due, first, to the hepatic and portal congestion, and later to the fall in blood pressure and the ischemia mentioned above. First, there is vomiting or retching and an evacuation of the bowels. After a few minutes the animal begins to stagger and falls over in collapse. The blood aspirated from the veins is found to be incoagulable.

Thus, we have seen that in guineapigs the cause of death resides in the musculature of the bronchials; in rabbits a similar cause is found in the circulation of the lungs; and in dogs, the hepatic circulation seems to be particularly involved. A most ingenious and plausible explanation for these is suggested in Wells's review. As a result of anatomical studies by a number of different workers, he states that histological studies of guineapigs have shown an astonishing development of the bronchial musculature, the finer bronchials consisting almost entirely of muscular tubes. In rabbits the pulmonary arteries present a remarkable degree of muscular development analogous to that of the guineapig bronchials; as far as dogs are concerned, he quotes Simonds as stating that the walls of the hepatic veins of the dog are different from those of any other animal, also, in showing a very high development of musculature; and Wells concludes that it is at least a reasonable hypothesis that the differences in these species in reaction to one and the same mechanism depend upon the distribution of nonstriated muscles. Interesting in connection with Wells's suggestion is the fact that Huber and Koessler have shown that asthmatic persons show a hypertrophy of the musculature of the bronchials the same as is found in the normal guineapig.

OTHER SYMPTOMS OF ANAPHYLAXIS

During the anaphylactic shock there is always a fall of temperature of several degrees, and this may be of much assistance in determining the occurrence of mild reaction, when other symptoms of shock are not strongly marked. There is also a leucopenia and a diminution in the polynuclear leucocytes.

In addition to guineapigs, rabbits and dogs, horses and goats have also shown to be particularly sensitive to anaphylaxis. The lower monkeys, Zinsser states, are exceedingly hard to sensitize and when after repeated injections sensitization is accomplished the symptoms are usually mild and not unlike those prevailing in human beings; in fact Zinsser cites a single case in which edema of the face and a condition somewhat similar to serum sickness in men resulted.

DESENSITIZATION OR ANTIANAPHYLAXIS

In properly sensitized animals the result of a sufficient dose of antigen given at the proper time is very often death. When the time and quantity are so chosen that instead of death there is merely a severe shock the animals are immediately, thereafter, in a refractory condition; that is, they are no longer sensitive to further injections of the specific protein.

This observation was made by many investigators and was thoroughly studied by Besredka and Steinhard who named this immune condition antianaphylaxis. Besredka has also proved that this state of antianaphylaxis can be brought about by giving moderate quantities of antigen at a time just preceding the development of hypersusceptibility.

The antianaphylactic state, however, is not lasting, in a period between two and three weeks the animal becomes susceptible again.

HUMAN ALLERGY

The first suggestion that human hypersensitiveness was related to anaphylaxis as observed in animals came from Weichard and from Wolf Eisner in 1905-1906 in their discussions on the subject of hay fever. Meltzer in 1910, on the basis of the similarity between the bronchial constriction of asthma and that observed in animals dying in anaphylactic shock, suggested that true bronchial asthma was a phenomenon of anaphylaxis. Koessler at about the same time, and independently of Meltzer, made the same observation, and in 1913 reported a case of asthma caused by hypersusceptibility to hen's eggs.

While animals can apparently be sensitized only with proteins, human beings can become hypersensitive to nonantigenic, or nonprotein substances, even to nonorganic substances and to physical agents, such as heat, cold, and light as described by Duke.

It is assumed now by most investigators, to use the term anaphylaxis only where there is a positive antigen antibody reaction such as in the experimental animal anaphylaxis, and allergy to be used broadly to include anaphylaxis and also all other altered reactions like serum sickness, drug idiosyncrasies and others.

DIFFERENCES IN ANIMAL AND HUMAN ALLERGY

Active anaphylactic sensitiveness in animals occurs consistently as a result of treatment with foreign protein. In human beings it rarely occurs as a result of treatment, but does occur spontaneously in a large percentage of persons, and often before the patient has had apparent contact with the offending substance.

While no direct experiments were made actively to sensitize human beings, yet there are so many substances, protein and nonprotein, injected subcutaneously and intravenously in human beings without the appearance in any way suggestive of anaphylaxis, except in some cases where individuals become sensitive to salvarsan after a few injections. We have seen that among animals the easiest to sensitize are the guineapigs and that monkeys can hardly be made sensitive, it seems then that humans, anaphylactically, resemble the monkey much more closely than the guineapig. (A biological proof of evolution.)

We have seen that animals can be sensitized passively; that is, if you take the blood of a guineapig that is sensitized to egg and inject it into a rabbit, the rabbit will react anaphylactically to a first injection of egg. Whether men can be passively sensitized is hard to tell because these experiments being unsafe were not attempted. However, Ramirez reported a case where a normal person was transfused with six hundred c. c. of blood from a donor who was horse sensitive. Two weeks afterward, the patient went for a carriage ride in Central Park. Almost immediately upon entering the carriage she experienced difficulty in breathing which developed within five minutes into a marked case of bronchial asthma which was relieved by adrenalin. The asthmatic attack returned again in the evening. The patient was tested with food, epidermals, and pollens which were all negative; tests with a very dilute extract of horse dander, however, gave a hive one and one half cm. in diameter. The donor when tested with an extremely dilute solution of horse dander gave a reaction of six cm. in diameter.

Local passive sensitization, however, was proved to be possible by Prausnitz and Küster and confirmed by Coca and his associates. What we mean by local passive sensitization is this: If we take some serum from a person who is sensitive to goose feathers, and inject it intracutaneously in the arm of a perfectly normal person, that area of the skin will become goose feather sensitive and will give the characteristic wheal and erythema reaction to extracts of goose feathers.

Walzer and Kramer (2) have very ingeniously utilized this phenomenon in the following way. Testing young children, cutaneously or intracutaneously is sometimes an utter impossibility, they fight so vigorously. Also in cases of general urticarias and eczema, where there is no healthy part of skin surface to perform the tests, they take about five c. c. of the patient's blood, the serum of which they inject into the arm or forearm of the mother or of some other normal individual, and instead of testing the patient directly they test the patient indirectly by applying the tests in the area where the patient's serum was injected.

Coca (3) tells of another very clever use that Walzer is making of this local passive sensitization, and this is to prove the gastrointestinal permeability. He sensitizes the skin of a normal person by injecting it with the serum of a patient that is sensitive to some edible protein, such as fish or egg. The individual then ingests some of the specific food and within three minutes to one hour or longer, a wheal with a zone of erythema develops in the passively sensitized site. At the time of the report Walzer was successful with only two proteins.

HEREDITY IN HUMAN ALLERGY

Heredity in animal anaphylaxis plays no part at all. In those cases where the offspring of sensitized pregnant animals has been born sensitized it is simply due to a transmission of the antibodies of the mother to the offspring. In human beings, however, heredity plays an important part in the development of sensitiveness. Cooke and Vander Veer studied the subject of heredity in human allergy very extensively and found that 48.4 per cent. of the sensitive cases have a traceable history of inheritance. According to them a child is not born hypersusceptible but its susceptibility is developed some time after birth. They also found that where both parents are allergic, about sixty-nine per cent. of the children will also be allergic, and their hypersensitivity will develop before their fifth year. In those with a single hereditary history the most frequent age for the development of this condition was between the ages of ten and fifteen years, and in those with a negative history, twenty to twenty-five years was the most frequent age for the appearance of the allergic symptoms.

PERMANENCE OF SENSITIVITY

Anaphylactic sensitivity in animals may last during the life of the animal, but as the life of the animal is short, and as the reaction becomes less marked with time, it is possible that if the animal lived for a long time the sensitivity might disappear completely. Sensitiveness in human beings is apparently permanent, as we know of cases of hay fever and asthma lasting from childhood to old age.

DEGREE OF SENSITIVENESS

Whereas sensitization of an animal may take place under the influence of almost inconceivably small doses of foreign protein—Rosenau and Anderson have succeeded in sensitizing a guineapig with one one millionth of a c. c. of serum—the shock dose must be considerably larger in the average case. This is not the case in human beings. Many persons sensitive to egg, fish glue, or pollen may react violently to the most infinitesimal doses. In a case reported by Baughton a fatal result followed the intravenous injection of one minimum of horse serum. Cooke reported a case where the intracutaneous in-

jection of one one hundredth of one c. c. of fish glue caused death. Duke reports a case where alarming symptoms followed the application of a little glue to the skin, and this in spite of the fact that it was washed off almost immediately.

While human beings, as we have seen, may react to many nonantigenic substances, such as, inorganic salts, silk, wood smoke, gasoline smoke, drugs, and chemicals, they are rather rare; the most frequent causes of human allergy are protein containing substances. By far the largest group responsible for human allergy is plants, especially their pollens which cause seasonal pollen hay fever and pollen asthma; orris root and pyretheum also cause perennial hay fever and asthma. Woodworkers and others who are handling sawdust of box wood, orange wood and many other woods occasionally suffer from asthma due to these woods. Next in importance come animal epidermals and then practically all foods.

Patients may react to antigens either by direct contact or when the protein is brought to the sensitive tissues of the patient by the circulation. What we mean by this is that when a patient is suffering from wheat asthma, an attack will occur either when he inhales wheat flour, where the wheat comes in contact with the bronchial mucous membranes or when he eats wheat bread, in which case the circulation will bring the wheat in contact with the bronchial mucous membranes.

By serum disease we mean the reaction to the injections of foreign serum, characterized by cutaneous eruptions, fever, painful joints, and edema, sometimes there is also albuminuria and with it oliguria.

Changed reactions of the body to various drugs, alkaloids, glucosides, organic compounds, and even to such simple substances as iodine, mercury, arsenic, etc., have been curious phenomena that have puzzled investigators for a good many years. Acquired resistance to drugs, so called drug tolerance, has been known for a long time, and every physician knows the enormous quantities of highly toxic substances that can be consumed by individuals who habitually used them. And just as there exists a drug tolerance, so is there a changed reaction capacity in the opposite direction; namely, a drug hypersusceptibility, a class of conditions grouped together under the term of drug idiosyncrasy.

In bacterial anaphylaxis we have two forms of reaction, one the reaction caused directly by the body protein of the bacteria which is allergic and is the cause of the allergic manifestations, such as asthma and hay fever in focal infection, the other, the reaction caused by bacterial products such as tuberculin, typhoidin, malein, etc. The tuberculin form of reaction is not allergic but inflammatory.

Symptoms of allergic reaction in human beings may be very mild so that there is only slight itching of the eyes, or they may be so severe that death may take place in a few minutes. Severe shock rarely occurs by the inhalation or ingestion of foreign protein; it occurs only as the result of the intravenous, subcutaneous or intracutaneous injections of protein. The following symptoms of reaction are described by W. W. Duke in his recently published book (1).

Shock.—With the onset of reaction, the patient usually complains first of generalized itching followed within a few minutes by pain in the top of the head or in the lower spine or both, and within a few moments by a feeling of total collapse in which the patient thinks he is going to die. Pain in the back and the head may become so severe as to cause the patient to cry out. General erythema and itching become intense. The face and tongue may swell and the patient becomes slightly or markedly asthmatic. Blood pressure usually drops and may reach an extremely low level. The pulse becomes weak and compressible and occasionally almost imperceptible. Upon appropriate treatment with adrenalin and intravenous injection of caffein, if indicated, recovery is usually prompt and complete. Severe reactions untreated, usually show improvement within thirty minutes.

Orbital symptoms.—These include puffiness and itching of the eyelids, slight redness of the lid margins, edema of the conjunctivæ and increased lacrimal secretion.

Nasal Symptoms.—Sneezing and pale swelling of the mucous membrane of the nose associated usually with excessive watery or clear mucous secretion are the usual nasal symptoms. There is occasionally frontal headache caused by pressure in the nasal sinuses or by pain in the top of the head as a direct result of general reaction.

Pharyngeal and oral symptoms.—Itching of the soft palate and pharynx, cough, less commonly edema of the uvula and soft palate, and swelling of the tongue are the usual oral and pharyngeal symptoms. In severe cases there may be swelling of the soft palate which may seriously obstruct respiration and require drastic measures for relief.

Laryngeal symptoms. — These include cough, hoarseness, pale edema of the membrane of the larynx, and epiglottis. This may vary in severity from simple hoarseness and cough to edema which may embarrass respiration and require tracheotomy.

Bronchial symptoms.—These include cough, bronchial obstruction with inspiratory and expiratory wheezing due apparently both to edema of the membranes and to spasm of the bronchial muscles, and the expectoration of clear, watery or mucoid sputum, rich in eosinophiles and often containing Charcot-Leyden crystals. This reaction may vary in severity from slight cough and shortness of breath on exertion, to obstruction so complete as to cause acute emphysema, spontaneous pneumothorax, and even a condition bordering on asphyxia. Patients may become comatose with the color of slate from asthma. Death from asphyxia, however, is rare in uncomplicated cases.

Gastrointestinal symptoms.—The most interesting of the abdominal symptoms is abdominal pain which may be local or general. It is often related to the eating of food and quite frequently appears a few moments after the ingestion of some particular food. The latter history always suggests that the reaction is a result of local contact. The pain may be so severe as that caused by almost any other acute abdominal condition and may cause the patient to writhe in agony. Whereas acute pain is a striking symptom, milder and more chronic pain is commoner. Other alimentary symptoms of interest are abnormalities in the quantity and acidity of the gastric juice, nausea, vomiting, bloating, diarrhea, mucous stools and pruritus ani.

Cutaneous reactions.—Cutaneous reactions may express themselves as erythema, pruritus, urticaria, and angioneurotic edema. Angioneurotic edema may appear on any area of the skin surface and also on some of the internal organs. When it causes obstruction to some important channels, such as the trachea and intestines, serious disturbances and even death may result.

Urologic manifestations (renal colic, irritable bladder).—The symptoms, frequent urination and bladder tenesmus, are rather frequently the result of general allergy, especially in the case of hypersensitiveness to foods. I have observed it in patients following the ingestion of fruits, vegetables, seafood and cereals. The condition may vary in severity from slight discomfort to pain and tenesmus which confine the patient to bed for months. Bladder allergy of long standing may be complicated by infection in which case the symptoms of cystitis obscure the diagnosis.

Hypotension.—Allergy is perhaps the commonest single cause of hypotension, since allergy afflicts probably as many as ten to fifteen per cent. of persons and since a blood pressure of from 90 to 110 is the rule.

Eosinophilia.—Koessler states that a differential count showing eosinophilia in excess of five per cent. is abnormal and that he found an eosinophilia in excess of it quite constantly in hay fever cases.

DIAGNOSIS

Family history.—Heredity is a great factor in human allergy, and if the father, mother or any other near relative of the patient had allergic manifestations, it should aid a great deal in the diagnosis.

Dermography.—Almost all allergic patients show the typical red line upon the slightest scratch.

Adrenalin.—The relief of symptoms by the administration of adrenalin should be a great aid in the diagnosis of allergy.

PROTEIN TESTS

Protein tests are our main reliance in the diagnosis of allergy. In allergic patients the skin is sensitive in a large percentage of cases. A specific protein introduced into the skin will show a characteristic reaction. The reaction consists of an urticarial wheal which has to be at least one half cm. in diameter with irregular edges and an erythema around it. These tests are performed in two ways, the cutaneous, where the protein is applied to a scratch in the skin, and the intracutaneous where the protein is injected into the skin. The intracutaneous tests are more delicate, but there is always the danger of a severe reaction.

As a rule, individuals showing skin reactions to a certain protein will show other reactions to the same protein; when they ingest it or inhale it attacks of asthma, hay fever or other allergic reactions will occur. However, in few cases a person may show strong skin reactions, but no other allergic manifestations. The reverse is also true, in some cases, where we know certain proteins, clinically, to cause asthma or other allergic symptoms and yet skin reactions to this substance will be negative.

TREATMENT OF ALLERGY

The treatment of allergic patients can be summarized in a few words: Remove the offending substance from the patient, or remove the patient from the offending substance. If almonds cause an attack of asthma whenever the patient eats them (and asthma does result from almonds in quite a number of cases) eliminate almonds from the patient's diet and he will be cured. Or if the patient suffers from seasonal hay fever due to pollens, remove the patient from the pollen infested places and the patient will not have any more hay fever.

But this cannot easily be done in all cases. When the offending substances are such important foods as egg, wheat, or milk you cannot very well eliminate them from the patient's diet. Hay fever pollens in season are practically thick in the air with the exception of very high altitudes or on the ocean. In these cases we have to produce a tolerance in the patient to the offending substance. This is done by making an extract of the specific substance and by injecting gradually increasing doses. In most cases we succeed in making the patient tolerant so that he can inhale or ingest the particular substances and yet be free from attacks.

Diverticulum of the Cardia of the Stomach*

FRANK PEARLSTEIN, M.D.

West New York, New Jersey

Diverticula of the gastrointestinal tract are of occasional occurrence. Those of the esophagus, duodenum, and sigmoid are rather the more frequent; with those of the sigmoid the most usual site in the alimentary canal. In the stomach diverticula are not often encountered, and when present usually affect the cardia, although the pylorus may also be involved. As in other locations this lesion may be congenital or acquired, and may give rise to symptoms or may be dormant, and discovered only in the course of a routine examination of the gastrointestinal tract. Especially is the congenital type liable to be silent, in common with many congenital abnormalities; for it is known that no matter what the congenital defect the patient may go through life without ever subjectively being aware of its pres-

*Read before the North Hudson Physicians' Society, November 30th, 1925.

ence. Of course, provided the abnormality is not incompatible with life.

A diverticulum may be described as a circumscribed more or less rounded pocket or pouch, or a bagshaped protrusion of mucosa from the lumen of

Fig. 1.—The cardiac area of the stomach, showing the diverticulum at "a" and the gas bubble surmounting it at "b" distinct from the stomach bubble.

the gastrointestinal tract. It usually occurs in a location where the muscularis is either anatomically or pathologically weak or absent. Of course the size of the pouch varies, and it may become as large as a pigeon's egg, and in the duodenum a case has been seen where a congenital diverticulum of the second portion attained a size equal to that of the stomach.

The cardiac end of the stomach has a musculature that is rudimentary (1). The longitudinal fibres

Fig. 2.—Oblique view of the cardia showing the communication between the diverticulum and the stomach lumen at "a".

are spread over the cardia, and are grouped adjacent to the curvatures. The circular fibres of the stomach are thick and abundant in the pyloric region, and spread and thin out as the cardia is approached. The oblique fibres in the cardia are likewise thin. So we have an almost flaccid sac of musculature in the cardia, as compared with the pars media and pylorica, and this readily explains the greater frequency of diverticulum in the cardia as compared with the pylorus.

The occurrence of congenital diverticulum is self-explanatory. There is an inborn weakness in the region of predilection, and so when the viscus involved is subjected to its physiological pressure increases the "locus minoris resistentia" "gives" and the lesion is produced. It is interesting to note that the case of Nauwerk, cited by Tupper (2), showed pancreatic tissue at the base of a diverticulum of the stomach, and so he concluded it to be a developmental defect. Undoubteedly the pancreatic tissue found was due to the presence of an accessory pancreas, and it may be mentioned here that an accessory pancreas, when present, is often situated at the lesser curvature of the stomach, and then may give rise to

Fig. 3.—Residue in the diverticulum after eight hours.

the congenital hourglass stomach, and so be mistaken for a gastric ulcer with hourglass contraction.

Acquired diverticulum in the cardia may occur as a result of pressure insults at the site of the lesion, by the trauma incident upon the swallowing of voluminous food masses or foreign bodies; or it may be due to trauma resulting in rupture of the muscularis. Perigastric adhesions with subsequent traction on the gastric wall may produce a diverticulum.

To be sure, there can be no typical clinical picture in this condition. Those diverticula that are acquired will more often give the picture of the primary disease, or the symptom-complex of the causative pathology will overshadow or offset the symptoms produced by the diverticulum. The congenital variety, as mentioned above, may not give rise to any symptomatology to bespeak its presence. Brown's case, mentioned by Tupper (2), gave a history of vomiting fresh blood on a few occasions. Röntgen

examination revealed evidence which was interpreted as being due to a penetrating ulcer on the lesser curvature of the stomach. Operation proved the lesion to be a true diverticulum of the cardia. Other symptoms that may be ascribed to this condition are pain, vomiting, and socalled sour stomach. Few of the reported cases showed hyperacidity.

My case, referred by Dr. D. V. Vitale of West New York, was a woman of forty-three who complained of severe burning sensation in the epigastrium immediately after eating, and sour eructations. Otherwise she had always been well, and there had been no weight loss, pain, or vomiting. Physical examination was negative. Fluoroscopic examination showed a low atonic stomach, and in the cardia a small sac was seen to fill with the contrast substance. Because of its location under the costal arch palpation under the screen was impossible. The illustrations show the pathology very plainly, and it is seen that the sac is surmounted by an air bubble, and that it communicates with the lumen of the stomach. The sac remained filled up to eight hours after the ingestion of the contrast meal. Gray's case (3) showed a residue in the sac up to one hundred and forty-four hours. The stomach showed no delayed emptying, and the rest of the röntgen examination of the gastrointestinal tract was negative. On the above röntgen findings a diagnosis of diverticulum of the cardia of the stomach was made.

The diagnostic points of diverticulum is this region are, the soft contour of the pouch, its pliability (when accessible to direct palpation), its smoothness, and the finding of a residue after the stomach has emptied. When palpation is feasible it is found that the lesion is not tender to pressure.

Clinically, and very often röntgenologically, this lesion is most often confused with ulcer, and differentiation is difficult, and many times impossible. In favor of ulcer, there is the clinical picture, the tenderness of the niche to pressure, the presence of indirect röntgen signs of ulcer, as residue, hyperperistalsis, spastic incisura, or organic hourglass. Withal, diverticulum is a condition which is extremely rare in the stomach, but it should be kept in mind when lesions of the cardia are considered, for ulcer in this region is very uncommon.

A thorough review of the literature brings out only thirty-eight reported cases of diverticulum of the stomach, and for this reason I believe that it is of sufficient importance and interest to add this one to the few already in the literature.

A Statistical Study of the Diagnostic Value of Hypoacidity

WILLIAM W. SAGER, M.D.
and HOWARD R. HARTMAN, M.D.
Rochester, Minn.

Four hundred and twenty cases were selected in which hypoacidity was present, all other factors being disregarded. The free hydrochloric acid varied from 4 to 20. The statistics were then analyzed to show the frequency of occurrence of various diseases in the series. Much work has been done since the practical introduction of the gastric analysis to the medical profession about 1870, on the degree of acidity or the presence of anacidity, associated with various diseases. Here our object is to show how great a degree of frequency we may expect of any one disease in a group of cases selected solely because of the presence of a subnormal concentration of free hydrochloric acid in the gastric contents. The cases selected were those in which the stomach tube had been used once following the ingestion of an Ewald testmeal one hour previously.

In a previous paper 492 cases of anacidity were similarly analyzed. Such results as are of value for the purpose of contrast or comparison will be given.

In the analysis of this group of cases, some difficulty arose from the complexity of diagnosis. That assigned when the patient came to the clinic was not always in harmony with, or did not always account for other complaints, which were, however, most frequently of minor importance. For purposes of grouping, that diagnosis was assigned which explained the symptoms from which relief was sought. If, however, malignant disease or disease of the gallbladder was diagnosed, the case was grouped under those headings, precedence being given in the order named.

Functional nervous disease.—One hundred fifty-eight cases were of functional nervous disease (37.6 per cent.). Various interpretations of this large number of cases may be given. The part played by the emotions in producing partial inhibition, as pointed out by Venables and others, the effect as pointed out by MacDaird, Campbell and Hern, of the sedentary life and reduced physical fitness of many of the patients of that type, the fact that only one analysis was made, the second frequently showing slightly higher quantities of acid, all probably have a bearing on the incidence of hypoacidity in cases of functional nervous disease, and the occurrence of so high a percentage in this series. Another factor to be considered, as pointed out by Bennett in discussing hypoacidity, is the presence of hypochlorhydria in persons in perfect health. This series shows a marked increase in the cases of functional nervous disease compared with a similar group in the series of 492 cases of anacidity studied. In the earlier series only eighty-seven cases of functional nervous disease were found.

Cholecystitis.—There were sixty-seven cases of cholecystitis. It is generally stated that there are changes in the gastric acids associated with disease of the gallbladder, although there is a difference of opinion as to the degree of solidity most often found. Gatewood, Leva, Rhode and others have found hypoacidity and anacidity most common in cases of cholelithiasis and cholecystitis. Gatewood, in reviewing a series of 192 cases of disease of the gallbladder, found achlorhydria or hypoacidity in forty-five per cent. Griffiths and Simitsky have said that hyperacidity and hypersecretion occur in disease of the gallbladder, Griffiths attributing this abnormality to a vagal reflex. In comparing the percentage of cholecystic disease found in this series with that found in the series of anacidity studied, very little difference is found. The percentage in the series of anacidity was 18.11; in this series it was sixteen.

Malignant disease.—There were seventeen cases of unquestioned malignant disease. One case that should be included was questionable but probably malignant. Of the seventeen cases, twelve were carcinoma of the stomach; one was multiple malignant disease of the abdomen, one carcinoma of the umbilicus, one carcinoma of the esophagus, one carcinoma of the transverse colon, and one abdominal carcinomatosis. The case in which the diagnosis was questionable was one of a large abdominal tumor, that was probably malignant but was not operated on.

A brief mention of some of the work done on the relationship of malignant disease of the stomach and acidity is of interest here. One of us observed, in reviewing a large number of cases, that free hydrochloric acid was found in about one half. This work was corroborated by Friedewald and Bryan later. The situation of the malignant neoplasm in the stomach, according to Hartman's findings, did not influence the degree of acidity. In a review of eighty cases it was found also that a patient with resectable carcinoma of the stomach has a forty-four per cent. chance of living five years after operation if anacidity is present. The chance of a similar patient with free hydrochloric acid present in the gastric contents is only half as favorable.

From a diagnostic viewpoint, the foregoing results are interesting. In the series of cases of anacidity previously referred to, there was found a 20.53 per cent. chance of malignant disease being present, while in the present series there is but a 3.1 per cent. chance.

Miscellaneous cases.—In contrast to the results obtained in the analysis of cases of anacidity, no cases of pernicious anemia were found. In the cases of anacidity, 11.57 per cent. were cases of Addison's anemia. In the present series twenty-eight cases of peptic ulcer were found, one of gastrojejunal ulcer, and one case in which the diagnosis of peptic ulcer was questionable. This shows a decided increase, as was to be expected, over the percentage of ulcers found in the cases of anacidity. Thirteen cases of syphilis were found. This group included but one case of gastric syphilis.

The remaining cases were scattered and probably only accidental, having no relationship to the hypoacidity other than a coincidental one.

TABULATION

DIAGNOSTIC DISTRIBUTION OF 420 CASES OF HYPOACIDITY

	Cases
Functional nervous disease	158
Cholecystitis	67
Malignant neoplasm	17
Questionable malignant neoplasm	1
Peptic ulcer	28
Gastrojejunal ulcer	1
Questionable peptic ulcer	1
Syphilis of the central nervous system	9
Gastric syphilis	1
Visceral syphilis	3
Chronic constipation	18
Appendicitis	11
Paroxysmal tachycardia	2
Hypertension	5
Dysmenorrhea	1
Goitre	9
Gastroenteritis	1
Epilepsy	2
Septic tonsillitis	1
Hernia	4
Arthritis	8
Amebiasis (Entameba histolytica)	1
Diverticulum of sigmoid	1
Nephrolithiasis	1
Glomerulonephritis	1
Incomplete abortion	1
Psychosis	2
Salpingitis	3
Uterine fibromyoma	3
Postinfluenzal debility	1
Cardiac extrasystoles	1
Pancreatitis	2
Retroversion of uterus	1
Pyonephrosis	1
Osteomyelitis	1
Angina pectoris	2
Endocarditis	1
Pulmonary tuberculosis	2
Lymphosarcoma	1
Nicotinism	2
Arteriosclerosis	2
Tuberculous peritonitis	1
Tumor of the bladder	1
Prostatitis	2
Pregnancy	1
Oral sepsis	2
Prolapsed ovary	1
Chronic intestinal obstruction	1
Myxedema	1
Chronic myocarditis	1
Mental deficiency	1
Secondary anemia	1
Indeterminate	26
Negative examination	3

Gallstones*

EDWARD L. KELLOGG, M.D., F.A.C.S.

New York

(*Concluded from page* 102)

It may be most readily demonstrated between the two heads of the sternomastoid muscle where the nerve lies most superficially as it turns around the anterior scalenus muscle (Mussy's point).

Gallbladder tenderness may be elicited by hooking the fingers under the ribs in the gallbladder region: by pressing deeply, while the patient takes a deep breath (Murphy): or by jarring percussion, produced, by holding one closed fist firmly against the costal margin, while it is struck sharply with the other. Jordan-Lloyd use a "deep prod" with the closed fist, over the gallbladder region, while Pottelschek places the four fingers of the right hand, passively, over the region to be explored, and presses them down firmly with the fingers of the other hand. It may be possible to outline the fundus of a distended gallbladder by percussion, to recognize a peritonitic rub by auscultation, and to determine the fixation or restriction of the side by inspection.

Muscular rigidity and skin sensitiveness are usually found upon palpation of the right hypochondrium, the maximum tenderness at the point where the ninth intercostal nerve penetrates the rectus muscle (on a line, just below the osteochondral junction of the ninth rib, horizontally towards the median line). These signs are present during the attacks and may persist for an indefinite period.

The gallbladder may become distended with obstruction of the cystic duct. In common duct obstruction it is usually contracted if due to a calculus, but distended if caused by malignancy, or outside pressure (Courvoisier's Law).

Enlargement of the liver has been described by Charcot and Naunyn as being seldom absent, while Kehr considers it uncommon, Ortner believes that many cases of stone in the common duct cause enlargement of the liver without other symptoms. It is certainly not uncommon to find the liver palpable at examination and moderately enlarged at the operation, although in cases of long duration it may be contracted. In Tietze's observations made by sectioning the liver at operation (3) the specimens always showed pathological changes varying from a leucocytic infiltration around the bile capillaries to acute yellow atrophy and biliary cirrhosis.

RÖNTGEN RAY

Improvements in x ray technic are responsible for the growing importance of this method of diagnosis. Direct demonstration of gallstone shadows can hardly be expected in fifty per cent. of the cases, when we consider their usual composition. The indirect findings, shown by adhesions distorting the cap, duodenum and hepatic flexure of the colon, or in the outline of a distended and thickened gallbladder, furnish valuable information of gallbladder disease but not necessarily of gallstones.

Palmer (4) finds that the presence of direct and indirect evidence is sufficient to establish the diagnosis in ninety per cent. of the cases.

While this may be usual in the work of certain röntgenologists, it hardly agrees with the experience of individual surgeons, particularly with reference to gallstones as distinguished from cholecystitis. It is certain, however, that recent advancement in the demonstration of the gallbladder shadow and of gallstones by the administration of tetraiodophenephthalein prior to examination greatly increases the proportion of positive findings.

LABORATORY FINDINGS

The laboratory findings are of limited value. A gastric hypochlorhydria with symptoms suggesting ulcer, is often due to gallstones. Absence of bile from the stools will help to differentiate obstructive from hemolytic icterus. Minute traces of bile in the blood may be detected by Hamil's method (5).

A capillary tube is filled with blood, sealed at both ends, and allowed to stand in a vertical position, until the serum separates from the clot. Examined against the light, it will show a yellowish tint if the slightest trace of bile is present.

Recent experiments made by Dr. A. V. St. George and Dr. A. Lincoln Brown of Bellevue Hospital have resulted in the development of a simple method of determining the icteric index of the blood serum which is of great value as a diagnostic procedure.

Hyperchlosterinemia is suggestive in cases with symptoms of gallbladder disease.

By Lyon's method of bile tract drainage, it is possible to obtain the gallbladder bile and to determine the presence of mucus, pus blood cells, epithelium, crystals and bacteria. So much has been said in criticism of this procedure, that I wish to emphasize its value, when carried out with Lyon's careful technic. Early microscopical examination is essential, as the sediment is soon destroyed by the pancreatic juice. In cases in which the digestive symptoms dominate the clinical picture, without apparent involvement of the biliary tract, and in the differential diagnosis of gallstones and ulcer, it is of great value.

It shows the infection of the biliary tract but does not prove the presence of gallstones.

COMPLICATIONS

Gastric complications may mask the lesion. Developmentally, the liver and its appendages are an outgrowth of the digestive tube immediately below the stomach, and the nerve centres in the cord are contiguous. Severe stimulation of one is easily transmitted to the other. The stomach is more susceptible to stimulation than the gallbladder, which accounts for the gastric symptoms frequently being first observed (McKenzie). Gastrospasm and pylorospasm occur. The latter is found frequently and is the source of pain in some instances. The pyloric ring

*Read before the Rockland County Medical Society. From the Department of Gastroenterology, New York Polyclinic Medical School and Hospital.

may become so hypertrophied, as to require surgical attention. Failure to relieve this complication is responsible for the persistence of symptoms in some cases after operation.

Adhesions may obstruct the pylorus leading to dilatation and retention.

Secretory changes are important. Kaufman states that hyperacidity is the rule, while Cohn (6) declares that subacidity is an almost constant symptom, that achlorhydria is a characteric result of obstruction of the gallbladder by stone, and that after cholecystectomy it is permanent. These findings do not agree with the conclusions of Ohly (7) but it is probable that absence of hydrochloric acid may predispose to the formation of gallstones by favoring infection of the duodenum and bile ducts.

My observations lead to the conclusion that gallstone disease in the sthenic individual of middle age is often accompanied by hyperchlorhydria, but with advancing years, the hydrochloric acid may diminish or entirely disappear, possibly due to exhaustion from over stimulation.

Obstruction of the duodenum is rather frequent and adds to the symptoms of pyloric obstruction, the copious regurgitation of bile, or gives rise to the typical symptoms of duodenal stasis and toxemia.

Fistula between the gallbladder and duodenum may lead to the discharge of calculi. One such case has come under our observation at Gouverneur Hospital. Stones discharged by this route may lodge at the inferior angle or at the duodenojejunal junction, in the lower ileum or colon causing obstruction.

INTESTINAL COMPLICATIONS

Acute or chronic appendicitis is a frequent complication. It may be due to a spread from one to the other by hematogenous or lymphatic routes, but in many instances there is probably a common cause in stasis and infection of the right colon. The differential diagnosis is difficult, when the appendix occupies an abnormal position in the liver region. If adhesions have not formed, inflation of the colon may cause a painful appendix to change position. Leucocytosis points to the appendix rather than to the gallbladder.

The pain of colitis occasionally simulates cholelithiasis. Examination of the stools and the increased discomfort upon inflating the colon, renders the diagnosis clear.

Obstruction of the intestines, by gallstones, was reported by Morestin, in 242 collected cases (1906). The stones usually became encysted close to the ileocecal valve.

Fistulæ between the gallbladder and colon occurred fifty times in Naunyn's group of 384 cases (of fistulæ).

Pancreatitis was found by Mayo, 141 times in 2200 gallbladder operations. Opie's experiments show that it may follow obstruction of the ampulla of Vater, by a calculus, with regurgitation of bile into the pancreatic ducts, but it also occurs without evidence of obstruction.

In Rosenow's experiments, the incidence of pancreatitis following injection of strains of bacteria from cholecystitis was five per cent. Deaver believes that it may be caused by lymphangitis.

During the presence of a calculus jaundice, the sudden occurrence of acute epigastric pain, muscular rigidity, nausea, vomiting and collapse, without leucocytosis, suggests acute pancreatitis, caused by stone in the ampulla of Vater (Murphy). In the less acute cases, the most important subjective symptom is colicky pain in the upper abdomen, radiating to the left costal arch, spine and left shoulder, accompanied by swelling at the side of the pancreas. A pale green discoloration of the skin has been described, around the umbilicus and in the lumbar region, which gradually disappears. Hematemesis may occur.

In chronic cases information is obtained from the fatty stools, alimentary glycosuria, and possibly the Cammidge reaction.

By direct examination of the pancreatic juice, obtained with the duodenal tube, it is possible to determine the presence or absence of the ferments and to estimate their activity.

CANCER

Cancer may result from the irritation of gallstones. Schroeder, in 1150 autopsies, found 141 cases of gallstones and in twenty of these there was cancer of the gallbladder or ducts.

Keay reported fourteen out of 149 cases of gallstones at Guy's Hospital.

Lichtenstein has called attention to the importance of enlargement of Virchow's gland (behind the clavicular attachment of the sternomastoid muscle) in differentiating malignant, from gallstone obstruction, of the common duct. Kehr adds to this, the enlargement of the jugular glands.

TREATMENT

Medical treatment is indicated—as a prophylactic, when one or more attacks of catarrhal icterus have occurred: following operations with a return of indefinite symptoms: for elderly people and those having constitutional conditions greatly increasing the risk of operation, such as high blood pressure, advanced kidney or heart lesions and threatened apoplexy. Normal bile is the only effective gallstone solvent in the human body.

It is desirable to maintain a continuous and copious excretion of bile, and as food stimulates gallbladder contraction, four or five small meals are given daily and a little milk, during the night.

A glass of beef tea is given before retiring since the extractives are active biliary stimulants.

The foods to be avoided are those rich in cholesterin and those which easily ferment, such as eggs (the yolk contains one half per cent. cholesterin), fats, butter, cream, spiced foods, fried foods, brains, sweetbreads, liver, kidneys, goose, duck, game, stews and gravies, fat fish, such as salmon and blue fish, peas, beans, lentils, pies, mayonnaise, alcohol, coffee and cocoa.

Those allowed are roast and grilled meats, free from fat, cereals, vegetables (except those prohibited), fruit, skimmed milk, bread in moderation, alkaline mineral waters, clear weak tea.

Water thins the bile but should not be taken iced. Two glasses of hot water may be given an hour before meals. Keay recommends two quarts of water by rectum on alternate days, to be retained as long as possible.

Strong purgatives should be avoided, but the

bowels may be regulated by giving the natural or artificial Carlsbad Sprudel salts in hot water twice daily.

Glycerine (pure and neutral) is said (by Mayor) to be a powerful cholagogue and helpful in colic. He states that a relatively large dose (three quarters to one ounce) will frequently terminate an attack, and a dose of one sixth to one half ounce daily in alkaline mineral water tends to prevent recurrence.

Olive oil aids by diminishing hyperchlorhydria and stimulating the flow of bile.

Sodium salicylate and the bile salts (sodium glycocholate and taurocholate) stimulate the secretion of bile. The salicylate is also an effective anodyne in some cases and is said to reduce the size of the liver and to act as an antiseptic.

Mercurials, podophyllin and medicinal soap increase the excretion of bile.

Sodium succinate prevents attacks of colic for long periods of time, probably by thinning the bile.

Hexamethylanimin (urotropin) is recommended for its antiseptic effect. (How it acts in an alkaline medium is not explained.) It is given in solution, two grains to the ounce of water and sipped slowly during the day (up to seventy-five gr.).

Duodenal irrigations and bile tract drainage are of considerable value but must be used regularly.

During an attack there is no substitute for morphine and atropine hypodermatically, with cautious inhallation of chloroform.

Some relief will be obtained from continuous warm baths or hot stoupes applied to the liver region.

Leuboullet recommends an enema of antipyrine and laudanum.

SURGICAL TREATMENT

When we consider that with stones in the gallbladder, the operative mortality is from three to five per cent. and that the complete surgical cures are seventy-five per cent. or higher, while according to Naunyn medical treatment shows forty per cent. of cures and a mortality of 4.6 per cent., there is little justification for postponing surgery, with the possibility of stones lodging in the common duct, increasing the mortality to forty-five per cent.

It is my belief that all cases of gallstones should receive prompt surgical treatment, even when discovered by accident, and in the absence of symptoms, excepting only those in which there is an unusual hazard in operation and a ready response to treatment.

The following points I deem important: free incision, adequate drainage, a vertical incision in the favorable case, sparing the eighth and tenth nerves if possible: a Mayo-Robson or Bevan incision when necessary, the upper angle being carried as close as possible to the costal arch and extended quite to the median line to favor rotation of the liver.

Cholecystectomy is the choice of most surgeons in uncomplicated cases, but the last word on this subject cannot be spoken until we understand more fully the function of the gallbladder and the cause and ultimate result of the dilatation of the bile ducts after cholecystectomy.

Rejuvenation

MALFORD W. THEWLIS, M.D.
New York

Old age being characterized by degenerative processes, we must give our attention to the prevention of their premature occurrence; nothing will regenerate the organs, but it is possible for degenerated organs to function in harmony as they do in normal old age. These senile mutations are not due to diminished secretion of the interstitial cells, as many have claimed; thyroid, anterior pituitary and suprarenal changes are as much involved as are those of the testicles. Factors such as chronic intestinal autotoxemia and focal infection undoubtedly help to hasten senile degenerations. Changes in the testicles seem to have somewhat monopolized attention, yet they are no more important than are the changes in other organs.

If old age were due to this diminished internal secretion of the gonads we could accomplish a great deal through endocrinology; the problem is not so simple. So many factors determine these senile changes that we must study the situation from every angle. Diseased conditions such as focal infection, disturbances of metabolism, to say nothing of syphilis, tuberculosis and chronic intestinal autotoxemia play an important part. Diet, exercise, occupation and heredity, the mental state of the patient and his economic position, all have to be considered. An old man may be dependent upon his children because he is unable to work. Obsessed by his years and impending doom, he loses interest in life and this is reflected in his appearance. He is slovenly, his facial expression is worn, he does not try to hold himself erect, nor to walk steadily; he stoops and shuffles along. His children pay little attention to him; since he has no money he feels dependent, in short, he is drifting and submissive. If we knew his actual anatomic changes probably we should find no more degenerative processes in his structure than we should in another man of the same age, one who is active physically and mentally.

The word rejuvenation has always fascinated the

public and the lay press well knows it. The slangy expression "monkey glands" has too often been hurled at ridiculed ancients. There is no reason at all why Steinach's or Voronoff's notions should be printed in books for the layman; the proper method of broadcasting scientific theories is before academies of medicine or through medical journals.

Steinach's operation (1) was brought before the laity at a time when medical literature was scarcely aware of it. Since it was not practical for women, Steinach devised an x ray treatment which was said to accomplish the corresponding rejuvenescence. Steinach's experiments on rats have never been confirmed and one observer said that the animals were afflicted with scurf (which gave them the appearance of senility) of which Steinach's care cured them.

Considering the degenerative changes inherent to old age, we must realize that thus far nothing has been found that would correct them. In senility every cell in the body is involved and we know that these cells, especially those of the nervous system, cannot regenerate. To quote Child (2), "Some degree of rejuvenescence occurs, even in man, and different tissues differ as regards their capacity for rejuvenescence, the central nervous system being apparently least capable of regressive changes. This characteristic of the nervous system suggests the probability that the natural or physiological length of life in these forms is determined primarily by the length of life of the nervous system and that physiological death is primarily the death, the final state of senescence, of the nervous system.

"Physiological or natural death is not something which has originated in the course of evolution from the lower to the higher forms. All organisms, from the lower to the higher, from the simplest to the most complex, undoubtedly die of old age, unless senescence is compensated by rejuvenescence. In the lower forms the death point may never be attained under the usual conditions because the low stability of the substratum and the consequent low degree of individuation permit the frequent occurrence of a high degree of rejuvenescence. In the higher forms death becomes inevitable and necessary because the capacity for rejuvenescence is limited by the greater stability of the substratum. For this high degree of individuation man pays the penalty of individual death, and the conditions and processes in the human organism which lead to death in the end are the conditions and processes which make man what he is. The advance of knowledge and of experimental technique may make it possible at some future time to bring about a greater degree of rejuvenescence and retardation of senescence in man and the higher animals than is now possible, but when we remember that the present condition of the protoplasmic substratum of these organisms is the result of millions of years of evolutionary equilibration, we cannot but admit that this task may prove to be one of considerable difficulty."

Ancel and Bouin, about twenty years ago, advanced the notion that a man's virility was due solely to the secretion of certain cells in the testes. However, this has never been proved. Steinach called these cells the puberty gland. We know that Leydig's cells are not the only factor influencing virility. Steinach's idea is that at the cessation of activity of these cells, man becomes senile and at their renewed stimulation, he regains his youth. The Steinach operation consists of the tying of the ductus deferens combined with vasectomy. His idea is that the tying of the duct (not removal alone) causes, through back pressure and later inactivity, a wasting of the generative portion of the testis, with subsequent reproduction of the socalled puberty gland, consisting mainly of the interstitial gland (Leydig's cells). The increased formation of the gonadal secretion reactivates the entire endocrine system of the patient, causing clinical results, varying from nothing more than an endocrine tonic to an almost actual rejuvenation (Benjamin) (3).

Benjamin, like many others, assumes that senility is due to a natural occurrence, that is, to an acquired lack of gonadal activity (primarily or secondarily) with an accompanying disturbed function of the other glands. If this occurs early in life he speaks of premature senility. He asserts that the Steinach operation reactivates the endocrine system in the sense of stimulation, regeneration and the restoration of equilibrium. Few will uphold these suppositions.

Steinach's operation accomplished the same thing as does the operation of vasectomy performed several years ago for senile prostatic hypertrophy. While some observers now claim that they are obtaining good results from Steinach's operation, the actual evidence is that the closing of the seminal ducts does not rejuvenate an old man. Moreover, there seems no good reason to believe that we will ever accomplish this. No doubt some improvement follows these operations, because of the psychic stimulation; without doubt increased gonadal activity will produce temporary results in some instances, to be followed later by a hastening of senile degeneration. So that, in fine, the operation may do actual harm.

Steinach's method of operation is said to disclose a new principle; it is, however, a simple removal of the duct or its equivalent. Since the procedure is a simple one, why do not our surgeons perform it as a routine? They are always willing to grasp new methods. The reason is obvious; it does not ring true to their surgical judgment; it does not seem logical to them that the method will accomplish its purpose.

Destruction of the thyroid gland, anterior pituitary body or suprarenal cortex causes a loss of sexual power as does castration; it will be seen, therefore, that sexual weakness is not entirely due to the testes.

Steinach showed that it was more difficult to rejuvenate women and devised an x ray treatment which he applied to the ovaries, under certain conditions, which he thought would cause rejuvenation. Steinach believed that the female puberty gland was stimulated to greater activity by the x ray. The revitalizing effect achieved is said to be analogous to the result of the Steinach operation in man. According to the disciples of this theory, stimulation doses "must not be used too long as they may destroy the tissues." The most favorable period is said to be the menopause. Steinach believes that the x ray causes the sensitive gland to waste, leaving the sturdier interstitial or puberty gland intact. Besides

the x rays, Kammerer adds the use of heat for treating the condition.

Holzknecht claimed cures with x rays in women suffering from complaints incident to the menopause and for hemorrhage from the uterus. He noted remarkable rejuvenation. Wrinkles disappeared, the face of the patient rounded out and the skin was more elastic; the signs of rejuvenescence as in men after the performance of tying of the duct.

Kammerer (4) notes that the stimulating exposure results in nothing more than a withering of the Graafian follicles but should not endanger the interstitial tissue. Very weak exposures are gradually intensified until the desired result manifests itself. According to Kammerer, "Persons working in an x ray laboratory for years, physicians and nurses for example, have noticed that their inner secretion is stimulated and effects are brought about which, in general, resemble the effects of a rejuvenation treatment by x ray."

These notions advanced regarding x ray are directly counter to those of other scientists. Albers-Schonberg, Bergonie, Tribondeau, Regaud, Dubreuil, Gordan, Simmonds and many others claim that the x ray is detrimental to the male genital organs. Many observers have recorded the absence or the infrequency of spermatozoa in the semen following exposures of various degrees to x ray. It is a well known fact that sterility is common in x ray workers.

Moreover, according to Kammerer, the technic is so complicated that we must be supermen in order to apply it. We have röntgenologists, it is certain that it would be a simple matter for them to give the treatments, especially with the instruments of precision now available in modern x ray apparatus. Why is the technic kept a secret by the few men who are doing the work? Vasectomy is a comparatively simple procedure and certainly a few exposures to x ray would not be difficult.

It is asserted that no deaths have been reported to follow this operation. However, Mendel (5) noted after the operation that one of his patients had a psychosis with serious sexual irritability and sexual hallucinations followed by death. He warns that it is not without danger; that the operation causing a rejuvenation of the interstitial cells has never been proved and that experiments on rats cannot take the place of human experiments.

Schmidtgen and Cruber (6) noted that the so-called rejuvenation following the operation was not real; but it was a return of sexual desires. They believe that the operation is not justified; that it has never been proved that an animal lives longer after operation than it would have lived without it.

Wolbarst (7) notes that in senile patients the Steinach operation may cause a marked decrease in blood pressure and a feeling of well being. When the sex function has been extinct the operation has had no influence. In premature senile cases, according to him, there is no reason to believe that sexual functions have been stimulated. He further states that the operation is painless, involves no risk and but little loss of time.

Robert Oslund (8) by careful experiments, has found that the operation as performed by Steinach does not accomplish what has been stated for it.

There seems to be no end to Kammerer's faith in Steinach's operation (9). Among the cures he includes mental senility, improved memory and a faculty for retaining figures, names and faces. Deafness and eyesight improved; the skin became fresh and rosy, while the wrinkles disappeared. Bald men with very little hair have been observed to gain a downy growth which steadily becomes longer and thicker. The nails are stimulated to new life, kidneys and prostate are in better condition. Pernicious ulceration and cancer are said to be relieved. Kammerer states that cancer is due to old age and that rejuvenation cures it. One might ask why we may see malignant disease at the age of puberty. Kammerer also states that tuberculosis in rats was improved even when both lungs were almost completely destroyed. The operation brought about regeneration of tissues of the lungs. Brown-Séquard surely made no more claims for his panacea!

Gland transplantation has been an interesting study and several careful observers have noted satisfactory results, both in men and women. In 1921, Hammond and Sutton (10) reported a case of sex gland transplantation, the gland being taken from a subject who had just died of hemorrhage from rupture of the liver. G. Frank Lydston (11) was the first one who performed the experiment on himself. He claimed that the vitality of the component cells of the various tissues and organs is preserved after bodily death, the glands being preserved by refrigeration. In the transplantation performed on himself the material was taken from a subject eighteen years of age, who died seventeen hours before. On the eighth day the implant appeared to be a failure and Dr. Lydston asked Dr. Michel to remove the implanted tissues. On removal, the gland split, one half remaining attached to the tissues. Lydston asserted that as long as a vestige of gland remains, the secretion was formed and absorbed. He concluded that the manifestations of senility can be retarded and longevity probably increased by secretions resulting from gland implantation. In one case the previous gray hair upon the arms and breast and almost entirely gray eyebrows and beard became darker within a few weeks. Lydston believed that the operation was of great value for arteriosclerosis when not too far advanced. He reported cases (12) dating five years back in which the results were sustained.

H. Lyons Hunt (13) noted good results from sex gland transplantation. He has performed eighty-four operations and had only eight failures; two showed reaction and six were nontakes. He found that not only rheumatism but neuritis yielded satisfactory results in eighty per cent. of the cases. Hunt uses sheep's ovaries and ram's testicles for the transplants. In cases of actual senility he found that the mental processes waxed stronger; that memory, deafness and eyesight improved and that the procedure was successful in ninety per cent. of the cases.

Steinach believed that autotransplantation worked well and that it was not necessary to reinstate a detached gland at the very spot from which it was removed. He believed that as long as the transplantation was within the same organism there resulted a certain rejuvenation of the gland. He believed it

worked best in cases of premature senility; that by means of the reproduction of the interstitial tissue, which started as soon as the gland's abode was changed, a surplus of vitalizing tissue was formed which brought about rejuvenescence.

Voronoff (4) employed apes' glands in his work, while Brinkley said that he was the first to use goat's glands. Brinkley (15) said that arteriosclerosis as well as high blood pressure was returned to normal in 100 per cent. of the cases. We have heard nothing more about this interesting subject lately.

Tuffier, Paris, implanted ovarian tissue freshly removed from young women and transplanted it in twenty who had passed the menopause and in not one of them was there a return of menstruation or other evidence of rejuvenescence. Most of his 230 operations were autotransplants, removal of ovaries from the pelvis to other locations in the same woman. in the majority of women under thirty menstruation was reestablished but in only one of fifty-six over forty did the flow reappear. He believed that the results of autotransplants of ovaries were transient and he records no successful results from grafting from one woman to another. In many instances these transplanted tissues are found after months as a foreign body.

Robert T. Morris (16) in 1906 performed transplantation of ovaries with one apparent success. He reported the birth of a child in a woman from whom he removed the ovaries and in whom ovaries from another woman were grafted four years before. Morris was the first one to perform the operation and the first one to discontinue it, believing that good results would occur so seldom that the operation was not justified excepting in homoplastic work.

We have no conclusive evidence that sex gland transplantation will cause more than a brief rejuvenation. The number of cases reported in the literature are not many and it is necessary, before heralding a lasting cure, to have made observations over a long period of time. One physician reported twenty-two cases with excellent results while others are able to report as many in whom the results have been equally as good from other measures, such as from psychic stimulation, change of scene, change of mode of living, and association with younger people. Anyone who sees many aged patients will recall the same phenomenon. A transitory effect from gland transplantation often occurs until absorption of the transplant follows. Commercial extracts of a number of glands when taken by mouth give practically the same results as graft.

To show what sometimes occurs in old people: a man, aged sixty-five, had every appearance of being much older and was gradually failing; he met a widow of fifty whom he had known several years before and she became interested in him and they married. She happened to be comfortably situated financially and gave him a home and a substantial allowance each month. His rejuvenation was apparently as satisfactory as Steinach's method is supposed to be.

His interest in life increased, he took excellent care of his personal appearance. He walked daily, read interesting books, went to the theatre and even learned to dance. His appetite improved and he gained in weight; exercise in the open air improved his health; he regained his sexual powers and fortunately he was not obliged to undergo any special treatment.

We often see men of this type. Another patient, a professional man, rejuvenated himself; he analyzed his own case and found that he was becoming senile at fifty-five. He immediately changed his mode of living and determined to grow young again. Instead of associating with old people as he had, he saw only younger ones. He walked four or five miles a day, quickened his pace and held his body erect. He was careful of his personal appearance; he frequently attended the theatre, preferring musical comedies because they were cheerful. He learned to dance and several times a week danced with younger people. The change brought about was remarkable; he walked so fast that younger people had difficulty in following him. It was apparently a case of actual rejuvenescence; his sexual powers returned. This occurred about ten years ago and he is as young in appearance and action today as he was then. Is this not as encouraging as the reports from enthusiasts of gonadal transplantations?

Many physicians could relate as many cases of apparent rejuvenescence of senile patients due to change of their mode of living, together with a change of their mental attitude, as can the average observer as proof of the Steinach operation.

Nothing causes ageing more than worry, care, mental depression, with consequent mental deterioration. According to our findings on physical examination, many people are apparently older than they should be. It is due to psychic causes, usually a recognition that old age is present; this leads to a psychic depression which causes physical inactivity and lessened metabolic activity and slowed circulation. Psychic stimulation is one of the most valuable weapons we possess in treating the aged and psychotherapy will often accomplish as much as gland transplantation. In my opinion these surgical procedures affect the patient psychically quite as much as they cause him to grow young through the absorption of an internal secretion from a grafted testicle or ligated vas deferens. The advocates of these procedures usually add in their writings that the patient did not know that the operation was being performed and while this may be true in some instances, I believe the psychic effect is as important as the operation itself.

It should be remembered that increased sexual activity after the age of sixty is likely to bring about cerebral changes, apoplexy and angina pectoris. Occasional sexual intercourse can do no harm and we often find old men who improve in sexual power as a result of exercise and a change in the mode of living. Sometimes a younger woman will cause an old man to have an acute interest in life and completely change his mental and physical condition. Stimulation of a sense of pride and the will to live will materially help to solve many problems of old age.

The thoughts of a surgical operation that will rejuvenate a man must be considered from a psychic standpoint. When hope of rejuvenation is given, the old man immediately sees new horizons before him; he feels that he can live longer, that life can be made more interesting to him and that he may be of some

use in the world. Does it not seem that this psychic effect has as much bearing on the cure as has the operation itself?

Hope is the strongest psychic stimulant known and by encouragement we can materially assist patients in recovering from pneumonia and other diseases, besides giving them an entirely new aspect toward life. We are told that many of these operations have been performed without the patient's knowledge; they were done and improvement noted. About 1890 vasectomy was performed on elderly men all over the world in order to improve the prostatic condition. One of Steinach's disciples said that the reason why many were not improved by the operation was that the old men did not expect to be rejuvenated—therefore were not!

It seems to me that no ground is being gained in this direction of preventing premature senility by operation or x ray therapy. Newspaper reports are not to be encouraged to take the place of communications at medical meetings or through medical journals. No doubt in some instances gland transplantation has worked well for a while and the patients to use it on are young men who have lost their testicles through some accident. Morris showed a patient before the New York Surgical Society who had lost his testicles from mumps. A graft underwent absorption but had the effect of stimulating the minute remains of the testicle into new growths to half the size of a normal testicle. Even in some of these cases the results have been very unsatisfactory (17). Evidence seems to be accumulating to discredit all of these procedures. Steinach's notions have been contradicted by H. Stieve, Karl Sternberg, Professor Zeissl and others. Haubenreisser noted no effect from x ray therapy. All in all we have many guesses which are not substantiated.

On the other hand there are other measures which scientifically tend to offset premature senile changes. We especially refer to the prevention of infectious diseases in earlier life, the discovery and correction of focal infection, careful attention to the treatment of chronic intestinal poisoning, the prevention of cardiorenal disease. Besides these, occupation, pleasant surroundings, economic independence and more attention to the aged when ill, a general interest in the preservation of the elderly (gericulture) and a reasonable percentage of the attention ordinarily given to child conservation will invest old age with mellowness and a great degree of pleasure. Added to this, an understanding of the mind of the aged patient and a general hopeful attitude toward him, will solve many of the perplexing problems of old age.

Affections of the Epiphyses Peculiar to the Second Decade*

IRVIN BALENSWEIG, B.S., M.D.
New York

The second decade of life is a hazardous period in the life cycle of the child. It is a transition period during which there is an adjustment of the endocrine glands and their sequelæ, such as, fusion of the epiphyses with their respective diaphyses, sexual, mental and physical readjustment. During this period several epiphyses appear for the first time. The children are most active physically and are subject to varying degrees of traumatism. It is the stage of the socalled growing pains of the average physician and parent, be it a painful foot, knee, hip or back. The endocrinologist attributes the pain to a dyscrasia of the internal secretory organs; the internist either states that the child is perfectly well, or when pressed for a diagnosis he is apt to term it a rheumatic manifestation; the orthopedist who thinks in terms of traumatisms and mechanics is inclined to view the affection from his aspect alone. Thus we are confronted by three main ideas as to etiology; endocrine dysfunction, infection and injury. To dwell further on these etiologic factors would detract from the object of this presentation.

The following affections are all peculiar to the adolescent period. They are in the order of their importance:—epiphyseal separation of the hip (epiphyseal coxavara, traumatic coxavara); vertebral epiphysitis (painful adolescent kyphosis); Osgood-Schlatter disease of the tibial tubercle; apophysitis of the os calcis; epiphyseal separation of the lesser femoral trochanter; separation of the epiphysis of the anterior superior spine of the ilium.

Anatomical and röntgenological considerations of the above mentioned epiphyses.

Numerous diagnostic errors are apt to arise from

*Read before the Harlem Medical Association, February 3, 1926. From the hospital of the Ruptured and Crippled.

the lack of knowledge necessary for the recognition of the various epiphyses; their time of appearance, röntgen appearance and relationships to their respective diaphyses and the time of complete ossification.

1. The epiphysis for the head of the femur begins to ossify during the second half of the first

Fig. 1.—Case II. F. S., röntgenogram of the affected hip (July, 1923) showing widening of the epiphyseal line, softening of the juxtaepiphyseal region; area of cavitation and a barely perceptible displacement of the epiphysis.

year of life. The epiphyseal line persists until the fifteenth year, beyond this there is complete ossification. (I. Cohen.)

2. The epiphysis for the tibial tubercle arises as a downward projection from the upper tibial epiphysis or from two centres; the second being found to lie opposite the lower pole of the site of the future attachment of the epiphysis. When arising from two centres they fuse with one another in about a year and act as a single epiphysis. These appear as early as ten years and eleven months and during the eleventh year grow quite rapidly in size, and as a single epiphysis projects forward, being separated by a wide space from the shaft of the tibia. Union proceeds from above downwards, and from before backwards. Ossification is found to be complete by the eighteenth year.

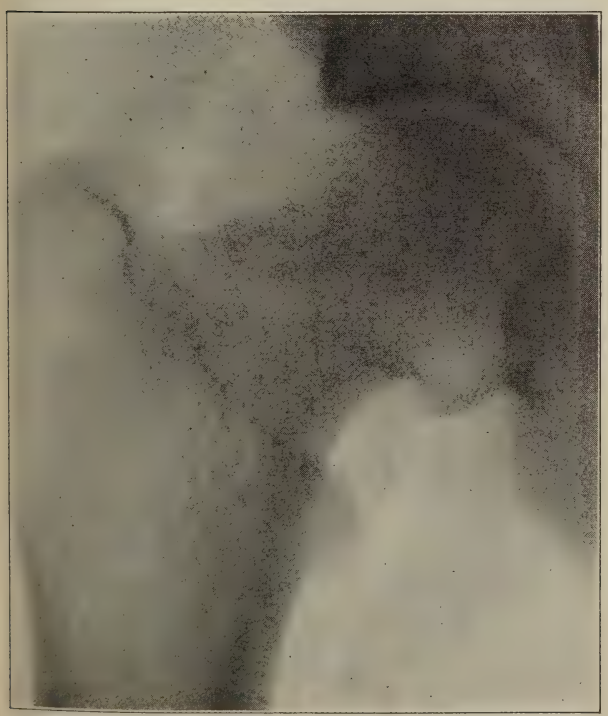

Fig. 2.—Case II. F. S., röntgenograph taken August, 1924, showing premature ossification of the epiphyseal line, complete healing of the process.

3. The superior and inferior epiphyses of the bodies of the dorsal vertebræ appear about the age of eleven and one half years according to Buchman.

Fig. 3.—Case III. A. H., showing the presence of a slipped epiphysis of mild degree.

"Appearing first in the lower dorsal region they later extend up and down the column as small triangular shadows adjacent to the anterior inferior and anterior superior angles of the bodies. Later they become elongated and appear as thickenings placed anteriorly and thin linear shadows extending backwards and terminating at the posterior angles of the bodies of the vertebrae, where they become thickened." Buchman. Fusion takes place about the twenty-fifth year.

4. The epiphysis for the posterior aspect of the os calcis is first observed about the ninth year, and becomes united with the body of the os calcis by the fifteenth year. Complete ossification occurs about the eighteenth year.

5. The lesser femoral trochanter appears as a scale like epiphysis at times as early as the ninth year, and is fused with the shaft by the sixteenth year.

6. The epiphysis for the anterior superior spine

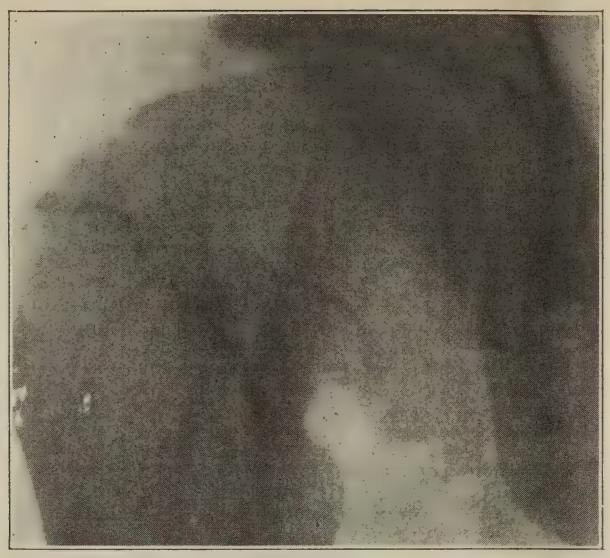

Fig. 4.—Case III. A. H., röntgenogram of affected hip taken three years after admission to the hospital. Large mushroomed head; premature ossification of the epiphyseal line; short and broad neck. Resembles late stage of Perthes' disease.

of the ilium is a part of the epiphysis of the entire crest of the ilium and is first observed about the fifteenth year and fuses with the ilium between the twenty-second and twenty-fifth years.

Epiphyseal separation of the hip. Occurs between the ages of ten and seventeen years more frequent in males and involves the left hip more than the right. The patients present a clinical history that may be considered pathognomonic of the condition. They may or may not be of the socalled status lymphaticus type; are found to be between the ages of ten and seventeen years, and are rarely totally disabled. Questioning elicits the following: that for one to two years prior to examination they have suffered occasional pain and stiffness at the hip or knee accompanied by an intermittent limp, which may or may not have followed a slight injury. The traumatism may have been of a twisting nature, a misstep, a stubbing of the toes or a fall to the ground. The symptoms may continue for months and then be either spontaneously arrested or progress to a stage of disability, the latter most often being due to a mild traumatism. The last injury is usually stressed and stated to be the sole cause for the affliction, especially when there is a possibility of instituting legal proceedings. The patient is observed to walk with a hip limp, with the limb externally rotated and slightly abducted but more often adducted. There is restriction of motion in flexion, abduction and internal rotation, with extension being free in most cases. Here we have a diagnostic sign peculiar to this condition when present, for, in no other intra-articular lesion of the hip do we find freedom in extension. Palpation reveals a fulness in Scarpa's triangle due to the anterior twist of the femoral neck. Mensuration discloses a shortening varying from one fourth to three fourths of an inch. In about fifteen per cent. of the cases there is a bilateral involvement.

Röntgenologic findings—During the early stages, the epiphyseal region is found to be widened, hazy and occasionally fragmented. The immediate diaphyseal portion may be observed to present a moth eaten appearance, or may reveal irregular areas of cavitation simulating röntgen appearances of bone abscesses. The diagnosis is confirmed by observing the following: "Under normal conditions the head rises sharply above the upper border of the neck; in these cases the elevation is lessened and the outline of the head and neck may form an unbroken line." R. Whitman. This may go on to complete separation of the head, the neck appearing shorter and broader due to external rotation of the shaft; and the epiphysis flattened as a result of its backward displacement. In the healed cases the following changes are noted: premature ossification of the epiphyseal line; increased deposition of lime salts obliterating the eroded areas; occasional diminution of the joint space due to absorption of cartilage of the femoral head and in some instances from the acetabulum; irregularity of the femoral head; varying degrees of coxa vara due to faulty reposition of the fragments; occasional flattening and mushrooming of the head simulating late stages of Legg's-Perthes' disease; and changes indicative of osteoarthritis. Nonunion has been observed in one instance.

CASE REPORTS

Case I.—H. G., male, aged fifteen years. Was first observed April, 1924, in the Out Patient Department of the Hospital for the Ruptured and Crippled stating that he was perfectly well until nine months ago, when, without cause, he suffered pain along the anterior surface of the left thigh. No history of either infection or of injury. Patient presented

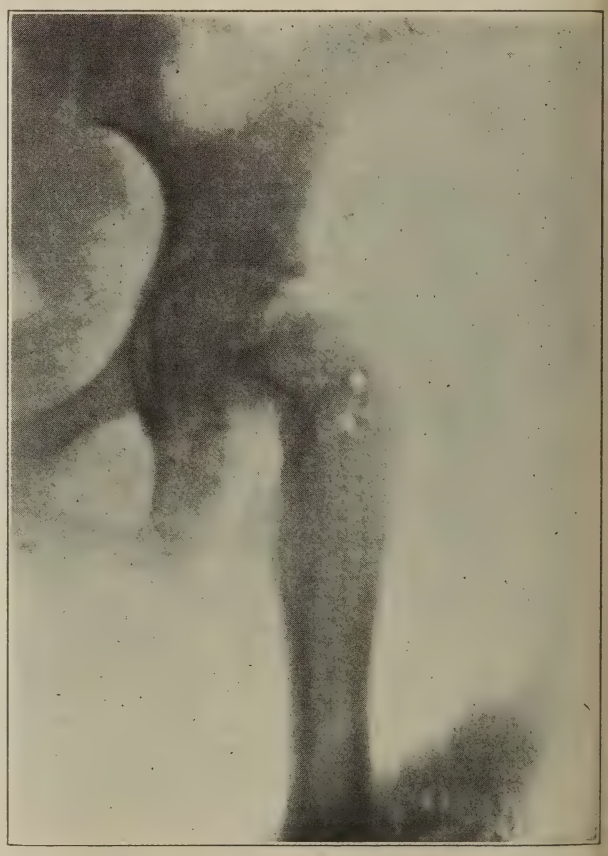

Fig. 5.—Case IV. V. C., röntgenogram taken prior to treatment showing the presence of a moderate degree of epiphyseal displacement. The femoral neck appears short due to the external rotation of the shaft.

himself because of occasional limp and pain of the left hip. Examination: overgrown adolescent male of the socalled status lymphaticus type, walked about unaided and without a perceptible limp. There was no restriction of motion and no atrophy, although there was approximately three sixteenths of an inch of shortening of the left lower extremity. Röntgenogram brought by patient showed a widening of the epiphyseal line on the left side with a loss of lime salts and fragmentation. The head was displaced slightly downward on the neck of the femur. The femoral neck was shorter and broader than that of the opposite side. Treatment suggested—application of a plaster spica bandage and reduction of weight. The patient was lost sight of until November, 1924, when the Social Service Department reported that there had been no change in his condition, and that he had received no treatment to date.

Case II.—F. S., female, aged thirteen years. Was admitted to the clinic July 27, 1923, stating that two months ago she received a slight injury to the left hip in a railroad accident. She had walked about with a limp and slight pain since the time of the accident. Examination revealed an overgrown adolescent girl walking about with a slight left hip limp with the limb in external rotation. There was some restriction of both internal rotation and abduction. No atrophy present. The affected limb measured one eighth inch shorter than the opposite one. No treatment was instituted, and when last seen, August, 1924, there was no restriction of motion of the hip, no atrophy, and, as previously noted, one eighth inch shortening. The x ray, at the time of admission, disclosed a normal right hip region, the left one presented a flattened appearance of the femoral head, a slight downward displacement of the epiphysis, widening of the epiphyseal line with loss of lime salts for a distance of one half inch of the diaphyseal region, and an appearance of cavitation of the inferior pole of the proximal end of the femoral neck. Röntgenogram taken August, 1924, shows a premature ossification of the epiphyseal line, disappearance of the cavitation and a normal joint space. This instance presents the characteristic röntgen findings of a low grade infection.

Case III.—A. H., male, aged thirteen. Admitted to the Clinic of the Hospital for the Ruptured and Crippled November 22, 1921, complaining of pain in the left hip of five months' duration, gradual in onset and without a history of either injury or infection. The condition was originally diagnosed elsewhere as an instance of Perthe's disease and a short spica bandage applied for six weeks with some relief. Physical examination at the time of admission revealed findings indicative of epiphyseal separation of the left hip region in one who was not of the infantile type. The hip was stretched under an anesthetic and a long plaster spica bandage applied. Patient reported from time to time to the clinic, and on August, 1924, he was observed to walk with a slight but perceptible limp, with same restriction of both abduction and internal rotation. Measurements disclosed a three quarters inch shortening of the affected extremity, one inch atrophy of the thigh, and one quarter inch atrophy of the calf. X ray findings—Film of June 22, 1921, showed a widening of the epiphyseal region, loss of lime salts on the diaphyseal side, some upward displacement of the neck of the femur. Röntgenogram of September, 1921, revealed the above slightly exaggerated; that of November, 1921, showed a complete solution of continuity at the epiphyseal region with a forward rotation of the femoral neck. This was completely corrected as disclosed by the picture taken at a later date. X ray of August, 1924, showed changes observed in cured cases of Perthe's disease, that is, large mushroomed head, short and broad neck.

Case IV.—V. C., female, aged thirteen years, school girl, was admitted to the hospital June, 1923, complaining of pain and partial disability of the right

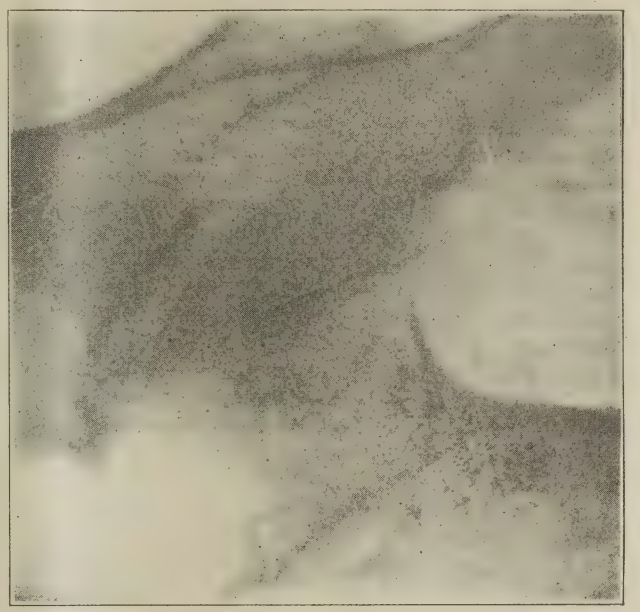

Fig. 6.—Case V. A. Z., röntgenogram of the affected hip taken sixteen years after operation for epiphyseal separation. Röntgenologically similar to late stage of Perthes' disease.

lower extremity. Duration nine weeks. At the time of onset, she was struck across the knees from behind, causing her to fall to the ground. She was assisted home and placed in bed, where she remained for three weeks. Soon after admission to the hospital, the affected hip was manipulated under an anaesthetic and a long plaster spica bandage was applied.

At the end of ten weeks the plaster was changed, maintaining the hip in an attitude for walking. Patient discharged at the end of five months walking with the aid of crutches. Since discharge she had been continuing treatment in the physical therapy department.

Examination August, 1924, and in October, 1925, showed that the patient was able to walk about without assistance, but with a right hip limp. Complained of no pain. The hip was fixed in a good walking attitude. The affected extremity was one inch shorter, the thigh presented an atrophy of two inches, and the calf of one inch.

The röntgenograms of June, 1923; the left hip was normal. The right hip region; outward rotation and upward displacement of the shaft of the femur; erosion of the proximal third of the neck; marked separation of the epiphysis.

Practical Therapeutics

Psychological Factors in the Treatment of Disease, with Especial Application to the Treatment of Paralyses in Childhood*

HENRY KELLER, M.D.

New York

PSYCHOLOGY AS APPLIED IN THE TREATMENT OF DISEASE

Some time ago in speaking of the general practitioner, I brought out the fact that in order to be successful in the treatment of disease one must use every means at his disposal, be it physical, mental, persuasion, suggestion or the method of autosuggestion, in order to establish a confidential communion with the sufferer. In no other way can a healer call himself a real physician. He may be a splendid theorist, stocked full of wisdom gathered from the autopsy table and pathological museum. He may also be a wizard in the handling of all modern apparatus, as well as take active part in the discussions taking place at various medical gatherings. However, notwithstanding all this, that physician is a complete failure at the bedside. He is all, but a physician, in the true sense of the term.

The dictum of Socrates uttered so many years ago, in the name of the Zamelxis' physician, still holds good today, as of yore. "All good and evil, whether in the body or in human nature, originate in the soul, and overflows from thence, as from the head into the eye. Therefore, if the head and the body are to be well you must begin by curing the soul, that is the first thing. And the cure has to be effected by the use of certain charms, and these charms are fair words, and by them temperance is implanted in the soul, and where temperance is there health is speedily imparted, to the whole body."

And he who taught me the cure and the charm, Socrates (1) continues, added a special direction: "Let no one," he said, "persuade you to cure the head until he has first given you his soul to be cured by the charm. For this," he said, "is the great error of our day in the treatment of the human body, that physicians separate the soul from the body."

Time and again have I emphasized the fact that the great danger of overspecialization in medicine is the fact that we treat a case, an interesting disease, a pathological phenomenon, but forget that the patient is a human being—with susceptibilities, eccentricities, idiosyncrasies, and emotions, each characteristic of which may modify the symptom complex to such an extent as to mislead the unwary. The treatment of disease after the diagnosis is established must also vary in accordance with the antecedents and environments of the sufferer.

Social status, sex and mentality, must all be taken into account. Drugs administered to the alien coming from Central Europe must, in order to be effective, contain ingredients which taste bitter, salty or sour. An ointment should by preference have a dark base, an odor and pungent. In children, on the other hand, medicines should always be sweet, sugary and tasty.

The ordinary patient expects a prescription following a painstaking examination, otherwise he feels that the physician has done nothing for him—with the result that he will probably land in the office of one's next door neighbor. The psychic effect of a prescription is great and should be utilized by the intelligent practitioner.

Some years ago a patient came to see me and after a thorough examination I decided that she was in need of plenty of water to wash through her kidneys. When I apprised her of that fact she told me that she can not tolerate any water, and that it tastes like poison to her. I soon switched my conversation to other topics in order to get her mind off the subject. A few minutes later I prescribed for her ℞ Syr. Rubi Idei ℥iv with directions that she take no more than five drops of the medicine in half a tumbler of water every three hours. Repeating, however, a number of times, with emphasis, that the medicine was very poisonous and that she should by no means take more than five drops to each dose. I then conducted the patient to the door, and in parting I again reminded her of the poisonous nature of the medicine, and also informed her that she should not return until the entire contents of the bottle was consumed. Four weeks later she returned, informing me of the fact that never before has she been given such wonderful medicine, and that she was all improved.

Little things may sometimes have great effect upon

*Lecture delivered at the University and Bellevue Hospital Medical College February 5, 1926, under auspices of the Neurologic and Orthopedic Departments.

the patient who is in your care and may at times effect a speedy improvement. In 1915, while a patient with spinal tuberculosis with paraplegia as a complication, was being prepared for an Albee operation I explained to the visitors in the amphitheatre the mode of procedure, the indications and counterindications. The patient was fifty-eight years old, not a very favorable subject for operation and before the anesthetist put the mask on the patient's face I heard the latter utter a prayer that, the Almighty may guide me and help me—spoken in a foreign tongue which I understood. When he finished his prayers I turned to the patient and replied Amen. He thereupon called upon the anesthetist to go on with the anesthesia as he, the patient, was ready.

After I was through with my work and he came out of the anesthesia he told me that my response to his prayer gave him assurance that I can do him no harm and that he feels that he is going to recover—and he did.

Injuries as well as deformities in children, as well as in adults, must be studied from a psychological point of view before determining the mode of treatment to be instituted, as I pointed out a number of times in my various publications.

Not all patients can be put on the inactive list even in fractures, and it is our duty to assort them properly and treat them accordingly. To quote a statement made by the writer on a previous occasion and published, with reference to fractures. "I am always concerned about the patient's return to his normal occupation at the earliest possible moment. For example, a patient having sustained a Pott's fracture is given an anesthetic and the fracture is properly reduced, immobilized by plaster of Paris bandages, and then an x ray is taken. If the alignment is good the patient, if he is a professional, business or office man, is permitted to return to his occupation after one week, walking with the aid of crutches, and a shoe raised three inches of cork sole on the normal foot, so as to keep off any jarring on the injured limb. An automobile pressed into service will be able to take the patient to and fro. The effect of such treatment upon the patient's mentality is remarkable. On the other hand, the same fracture sustained by a weak, overworked and exhausted housewife should be treated like the fracture sustained by the soldier upon the battlefield. She should be removed from her home to a hospital, for she is in need of mental as well as physical rest, both of which she cannot obtain at home surrounded by her old associations. If nothing else can keep her in the hospital, a Balkan frame is certainly impressive and should be resorted to" (2).

To those who are particularly interested in the study of psychology of the cripple and handicapped I beg to refer to the article of mine which goes into the subject exhaustively, showing there the influence of sex upon such deformities, and how to utilize that knowledge in the treatment—with the following conclusions: "To put the matter in concrete form it is necessary for the orthopedic surgeon to view his patients suffering from deformities from the psychological viewpoint, as well as from the point of view of physiology and mechanics, and acquaint himself with the subconscious motives activating those sufferers to seek relief, for only in that way can he deal with his patient thoroughly, scientifically, and successfully" (3).

W. Blanchard (4) in speaking of operative correction of bowlegs, points out that a primary consideration in the end results of any operation is the effect on the mental condition of the patient. He also calls the reader's attention to the dejected look of each patient with bowlegs before operation, and the self-confident poise of each cured case.

Only recently have I been invited to a wedding of a girl whose torticellis I have corrected by operation five years ago, and whom I have not seen since the removal of the plaster helmet eight weeks after the operation. Her improved demeanor and her change of poise since she first came to my office seeking relief was something that I shall never forget. She told me that the reason why she came to invite me to the wedding is the fact that she was convinced that, if not for the corrected deformity she never would have attained the anticipated bliss.

PSYCHOLOGY OF CHILDHOOD AND ITS APPLICATION TO THE TREATMENT OF PARALYSES

There are cases of paralyses quite frequent in childhood which may be due to damage either to the peripheral nerves as in obstetrical paralysis, or caused by spinal cord involvement as in anterior poliomyelitis. In these involvements the damage may be very extensive with extensive paralysis of the part supplied by the nerves implicated. On the other hand, there are many cases where the damage wrought by the onset of the disease has a tendency to subside, leaving only few muscles of the group originally involved to bear the brunt of the disease, while the other muscles recover their old time vigor, or some muscles of the group may be paralyzed while the others may be left weakened or paretic.

The latter cases are most amenable to commonsense treatment, and one can expect a great deal of improvement in such cases, provided the cooperation of the child can be obtained quite early in life, before permanent damage has set in the spinal motor centres caused by disuse of the parts. The most effective method to secure the active cooperation of the child is by the psychological methods hereafter set forth.

That early childhood is the most frequent age in which anterior poliomyelitis manifests itself is shown by the following statistics: Whitman, in giving his statistics of the age incidence in infantile paralyses shows that seventy-one per cent. occur in the first three years of age. The records of the Department of Health covering a series of 1,081 cases of poliomyelitis during the epidemic of 1916 studied with reference to the age incidence, show that the age incidence having the largest number of cases was two years.

Erb's palsy or obstetrical paralysis involves the upper extremity in the largest majority of cases. Though many cases are caused by compression, in the majority of cases the actual lesion is laceration due to over stretching of the nerves and their sheaths.

Tubby points out the important fact that it is only very rarely that total paralysis has been reported.

Tubby (5) cites statistics showing that Erb's palsy occurs once in two thousand births, alike in both sexes.

In order that one may treat a child intelligently one must realize that a child is not an adult in miniature,

as a good many seem to think, but that the mind of the child is an entity by itself, with its own laws. Only then can one succeed in entering into confidential communion with the child, whether it be well or sick. Movement, which though in later life passes out from the direct guidance of the mind, and becomes an automatic part of the central nervous system, is in early childhood dependent upon the brain integrity and mind, in order to develop normally.

Angell (6), in his interesting book dealing with modern psychology, brings out these facts very succinctly, thus: "The earliest objects of our volition are undoubtedly the satisfaction of the simple bodily needs represented by hunger and protection from the extremes of temperature. Then comes interest in securing control over objects at a distance from us by virtue of learning to move our eyes, our hands, and our bodies in such ways as will enable us to secure or to avoid particular forms of stimulation. In this manner it occurs that during the very early years of life we gain command over our more commonly used muscles. We learn to walk, and to talk, to write and to read, to reach for objects, to lift them, and to place them where we may desire. All these muscular accomplishments rest upon what we designate habit. These habits at the outset require the most persistent and careful mental control. After the movements have been performed a few times they tend to become more or less automatic, and after a sufficient number of repetitions they may pass almost wholly out from under the direct guidance of the mind, and be carried on by the automatic machinery of the nervous system, thus leaving the mind free to pursue its own further interests."

KINESTHETIC EQUIVALENT

Movement of the trunk as well as performance of an action is usually accompanied by some thought, or mental picture, or image or memory to suggest that movement, or action, which is equivalent to the feeling of the movement we desire to make. Otherwise we can not succeed in making it. This principle is termed in psychology kinesthetic equivalent. Baldwin (7) illustrates the principle in the following way: "This dependence of action upon the thought which the mind has at the time is conclusively shown in certain patients having partial paralysis. These patients find that when the eyes are bandaged they can not move their limbs, and it is simply because they can not realize without seeing the limb how it would feel to move it, but when they open their eyes and see the limb they can move the limb or limbs freely."

A patient can not speak when the cortex of the brain is injured in the particular spot which is used in remembering how the words feel or sound when articulated.

Many such cases lead to the general proposition that for each of our intentional actions we must have some way of thinking about the action, of remembering how it feels, looks, etc. We must have something in mind equivalent to the experience of the movement.

A child, therefore, can not perform a new movement simply by wishing it as he has no equivalent in his mind to proceed upon. But as he learns the action, gradually striking the proper movement one by one, oftenest by imitation, he stores the necessary equivalent up in his memory, and afterward only needs to think how words sound, to be able to make the movements or speak the words forthwith (8).

APPLICATION

One can therefore realize, without the need of a great stretch of the imagination, that the smaller the child when afflicted the greater the danger of the deformity becoming more persistent and therefore the need of early treatment in order to reestablish the association of the movement with the memory of the movement in the brain, or to establish the memory equivalent, as early and soon after the diagnosis is established.

Another important point which this above statement of Baldwin suggests is the fact that, in inducing the child to use the affected limb it is necessary to first stimulate the child's alertness by allowing it to use the unaffected limb, and then gradually encourage the use of the weak limb, and also that the child should be placed in such attitude as to see the attempt of the motion of the limb, for as we brought out before that the vision will help establish the movement equivalent in the mind—and thus aid in the recovery of the affected limb.

MODES OF APPEAL TO CHILDHOOD

Play is a tendency which is innate in the human in common with many of the animals, and it is therefore a very important means of finding favor with the child, and obtaining the child's cooperation with very slight effort.

"Play," says McDougal (9), "must be reckoned among the native tendencies of the mind of high social value. Children and the young of many species of animals take to play spontaneously without any teaching or example."

There are various theories to account for same. According to Professor Groos (10) the plays of animals and children are instincts which have arisen through the action of natural selection because, of their usefulness as a practice and preparation for life's later serious duties.

Others look upon the play tendency as a special instance of the operation of the law of recapitulation, in which the child retraverses in his play the successive culture periods of human history. While still others—led by Schiller and Spencer, play is the expression of a surplus of nervous energy. Some consider play as identified with the spontaneous expressions of the unspoiled and inexperienced mind.

Whatever the reason for this inborn tendency for play may be the fact remains that such inclination is found in marked degree, and that an intelligent physician can utilize this characteristic of childhood in the treatment of many deformities, and bring about improvements in certain defective organs without the patient's direct knowledge of the reason for such cooperation.

Games must be ordered according to the age and sex of the child, as pointed out by me (2) in a previous paper that, even in earlier childhood the difference between the masculine and feminine type manifests itself in the love for different games. The girl loves her domestic plays, her dolls, her make believe school, and a number of other such tame games.

Factors Facilitating Epileptic Seizures*

ALFRED GORDON, M.D.

Philadelphia

Among many problems concerning the pathogenesis and etiology of epilepsy, one especially appeals strongly by virtue of its practical value and that is the recognition of factors which condition epileptic seizures. During a period of ten years I endeavored to register attacks of epileptic convulsions in their relation to accidental or incidental situations which immediately preceded them. Records were kept of a series of two hundred cases in hospital and private work.

In forty cases convulsive attacks would make their appearance whenever there would be an omission or neglect in the care of the gastrointestinal apparatus, such as constipation or else diarrhea, formation of considerable amount of gas. In ten consumption of certain articles of food, particularly nitrogenous, such as meats and eggs, and in some cases fish food—have all been the provocative factors. There was a great variation in the individual susceptibility, as, for example, in some cases one of the food articles mentioned remained without effect but in other cases it played the rôle of a provocative agent soon after the ingestion (from one to three hours). In this group no evidence of a pathological state of the entire alimentary tract could be discovered. In twenty cases a chronic gastrointestinal disorder was present: Dilatation of the stomach, enteritis, hypochlorhydria or else hyperchlorhydria—all evidenced by röntgenographic and chemical studies. In these cases faulty combination of food leading to fermentation, putrefaction and local distress accompanied or not by pain—have all been observed in association with and preceding the onset of convulsive seizures. In several cases (ten) intestinal parasites were present and their expulsion was followed by considerable improvement, although there was no total disappearance of the attacks. On the other hand reformation of the parasites led to a greater frequency of the seizures.

These four groups of cases evidently belong to the toxic category. The metabolic vicissitude, the chemical substances, gaseous or liquid, elaborated during the process of gastrointestinal digestion are here apparently responsible for the cerebral upset or irritation which invariably resulted in convulsive seizures. The relation of toxicity to epileptic attacks is of course debatable. However, when the alimentary toxic element is manifest, the epileptic attacks may be considered as an anaphylactic crisis in which abnormal proteins enter the organism.

To the toxic groups belong also cases in which alcohol played a considerable rôle (fourteen in number). The use of wine, beer or brandy in these patients, even in small amounts, always resulted in convulsive seizures.

Eight patients presented a very interesting situation. In them the epileptic seizures occurred only at the end of the day upon the return from work when they felt exceedingly fatigued. Two of these patients observed that when on holidays they had opportunities to take prolonged promenades, the latter invariably were followed by attacks. In this group evidently undue physical fatigue was the provoking factor. What the exact mechanism is in fatigue which leads to cerebral irritation and consequently to epileptiform seizures is difficult as yet to determine unless we admit that exhaustion is accompanied by formation of noxious metabolic substances or by chemical disturbances in the internal secretory function of the endocrinological system which via the circulatory system reach the cortex. Twelve patients were in the adolescent period of life. They all suffered from epileptic convulsions at irregular periods. Being extremely poor, they were underfed; pallor of the skin and of the mucous membranes, great hunger, restlessness, irritability, insomnia were the symptoms present. The blood examination showed some evidences of anemia, such as diminution of hemoglobin (from 75-85) although there was no pronounced anemia. An unusual improvement in frequency and intensity of the attacks followed the amelioration of the physical condition brought about by the social charitable agencies in Philadelphia. How malnutrition may become the provocative agent of epileptic attacks, one cannot definitely say, although cerebral anemia has long been known as one of the etiological factors in epilepsy. It is well known from experimental physiology that compression of the carotids may produce loss of consciousness. In one of my patients (not

*Read before the National Association for the Study of Epilepsy, June 7, 1926.

considered in this group) during convalescence from a protracted case of double pneumonia there developed a convulsive seizure when he got out of bed and assumed an erect posture.

In twelve cases there was an insufficient number of hours of sleep. Whenever the individuals happened to have a poor or a very poor night averaging one or two hours of sleep, early on the next morning there would be convulsive seizure. So striking was this phenomenon that the patients surrounded themselves with precautions and when there was no tendency to fall asleep, one or two tablets of allonal or of veronal would be taken, and thus they averted the morning epileptic seizure. It is possible that in all such cases a congested state of the brain maintained through a sleepless night by a continuous cerebral activity is the cause of the cerebral irritation resulting in seizures.

Ten females presented an interesting and unusual coincidence of epileptic attacks with the change of the weather. Immediately preceding a storm and rainfall an attack would invariably occur. The phenomenon was so constant that the patients familiar with such possibilities would go to bed and keep some one of their relatives in the room to watch them in order to prevent injuries during the seizures. It is difficult here to explain satisfactorily the influence of variation in atmospheric pressure except perhaps by analogy with what takes place in the spinal cord in cases of caisson disease. According to one of the views concerning this affection there is congestion followed by stasis: high pressure drives the blood from the periphery to the internal organs especally to the nervous system. In our cases similar temporary changes probably occurred in the vascular supply of the cortex with the result of an irritation producing a convulsion.

In seventeen cases (all men) the following phenomenon was observed: on many occasions following a great physical effort the face would become purple and a convulsive seizure would occur: as, for example, in lifting heavy weights or in trying to reach objects at a certain height, or in leaning downward with the head low. In these cases we are probably dealing with a passive congestion of the brain resulting in a cortical irritation and consequently in convulsions.

Seventeen patients had convulsive seizures during induced variations in the pressure of the cerebrospinal fluid. In seven of them for therapeutic purposes or in the course of routine lumbar punctures for biological tests each withdrawal of small amounts of spinal fluid (five or ten c. c.) would be followed by an epileptic attack. Lériche, as it is well known, believes that the intracranial pressure in epilepsy is low. In order to raise the pressure I injected repeatedly in the spinal canal, five, ten, and twenty c. c. of physiological salt solution. Curiously enough and contrary to the experience in the former seven cases, an epileptic convulsion occurred after each injection. The conclusion that could be drawn from such contradictory findings is that hypotension as well as hypertension could be equally incriminated. Either factor produces a cerebral irritation which results in epileptic seizures.

In thirty cases various traumatisms played a significant rôle. I hasten to add that only the socalled idiopathic epilepsy is considered here but not the affection due to a proven damage of the brain tissue. In some of this group prior to the trauma epileptic attacks occurred on rare occasions, once in six months or in two or seven years. Following an insignificant trauma, such as a fall from three steps of stairs, an accidental fall on the pavement, a sprain of an ankle, a twist of the lumbosacral region, a fracture of the wrist in three cases—in all these instances there was a precipitation of the original convulsive attacks. It was strikingly evident that the trauma was the provoking factor, and the subsequent seizures were the result either of sudden alterations in the intracranial pressure, or of circulatory disturbances or else of sudden endocrinic discharges.

A survey of all the data presented here suggests the idea that they contain no specific value as far as the pathogenesis of the great affection called epilepsy is concerned. There are many other factors besides those observed in my two hundred cases. They are all of the same etiological importance. They are but circumstances favoring the outbreak of an epileptic seizure.

If we consider for a moment the fact that the very same occurrences, such as trauma, metabolic vicissitudes, hypotension or hypertension of the cerebrospinal fluid, etc., are not followed by serious morbid consequences in normal individuals, the above mentioned conclusion as to the absence of a specific value in these provocative factors finds its strong corroboration. The fact that in some cases they do and in others they do not condition epileptic attacks, demonstrates strikingly the truth that there are brains which possess so to speak a certain epileptic predilection (*epileptische Reactionsfähigkeit*) or rather a certain tendency of the cortical cells to molecular or functional disturbances, which under the influence of the above provocative factors become awakened. This apparently speculative contention finds its special confirmation in the history of traumatic epilepsy. In many instances of trauma even gross damage may never be followed by convulsive seizures, but in the epileptic cases while the trauma may produce small or diffuse structural or molecular or vascular changes in the cerebrum, the latter *per se* are not sufficient for the creation of an epileptic condition. Such a situation suggests the existence of a central nervous system which is fundamentally or inherently predisposed to irritative phenomena by virtue of special personal or family morbid characteristics. We are dealing in all such instances with a socalled "intrinsic epileptic predilection." What this intimate "predilection" means in terms of exact science or what precisely the molecular alterations in the cortical cells consist of,—all this escapes our observation as yet in spite of the fact that Ahrens (1) observed positive changes by means of Abderhalden's reaction. Although we are still working in uncertainties with regard to the pathogenesis of epilepsy, nevertheless the accumulated clinical, physiological and experimental data permit us with sufficient reason to admit that in this affection the function of cortical elements is unquestionably disturbed and that in forming a proper estimate of such disorders we must invariably bear in mind the personal and family antecedents and particularly the biochemical processes, the physiological, endocrinological, hereditary and psychic elements,

characteristic of each individual. That they are most important in the determination of the pathogenesis of epilepsy, can be seen from various therapeutic attempts and endeavors. Held (2) for example administered a serum extracted from dogs previously inoculated with the serum from epileptic individuals. His object was to neutralize the toxins of the epileptic or to influence favorably the endocrines. In four hundred such cases he obtained seventy per cent. favorable results. I, believing that the bloodserum is not the only fluid but the cerebrospinal fluid also participates in their distribution, utilized the latter for the treatment of essential epilepsy. I observed hemolysis when blood cells of one epileptic were placed in contact with the cerebrospinal fluid from another epileptic thus illustrating the fact that each cerebrospinal fluid contains substances which act specifically on another epileptic. Some (3) favorable and even extremely favorable results were obtained by me with regard to the character, intensity and recurrences, general health and mentality of some epileptics. Another observer, Lériche (4) obtained satisfactory results with intravenous injections of physiological serum.

A critical review of all such therapeutic attempts prove that they are all sound because they are based on well established scientific data; they also prove that there are undoubtedly many factors in the causation of epilepsy. Failure in a given case means that the particular etiological factor in that case escaped the investigator's notice. Success in a given case means that its etiological factor was traced and caught by me and therefore the method used was the appropriate one. The subject of essential epilepsy is therefore extremely vast; unceasing biological research in every direction is inevitably indispensable for the determination of the chief endogenous factor in each individual case of essential epilepsy.

From the mass of accumulated data which is actually bewildering one may conservatively draw this conclusion that the true pathogenesis lies in a special susceptibility of the cortical cells to irritation and this susceptibility is in all probability inherent either in a morphological or biochemical sense. Multiple factors are at the basis of the constitutional characteristics, and among them hereditary and congenital ones play the most conspicuous role. Excepting the cases with direct traumatic damage of the cortex, in all instances there exists the *epileptische Reactionsfähigkeit* of the brain mentioned above. Although the mathematically exact determination of the latter had so far escaped our efforts, we must nevertheless continue our work in the same direction bearing in mind at least this indisputable evidence that the existence of inherent constitutional elements indicate the direct road to preventable means and measures. Splendid examples of such a scientific attitude we find in the histories of pathological germplasms leading to endless varieties of abnormal states, and conditions in the progeniture, among which special and pathological tendencies of the cerebrum may be mentioned in connection with the subject under discussion. At this juncture the present study acquires a position of an intense prophylactic character rather than that of a curative character. On the other hand in view of the obscurity of the actual pathogenesis which confers a certain mystery on the above mentioned morbid predilection of the brain which produces epilepsy, the knowledge of the existence of some endogenous or exogenous factors which are apt to precipitate or provoke an epileptic seizure is of great value. Since we are helpless and impotent when we are confronted with the end results of pathological germplasms, our efforts must be directed besides prophylactic activities, chiefly towards removal or at least towards decreasing the intensity of those precipitating factors such as described in the present study. While the basal inherent creators of the disease are not amenable to alteration in the victims of the mysterious malady, the provocative factors are on the contrary to a great and even to a very great extent amenable to a minimization of their pernicious influence on the special dynamism of a brain which is fundamentally ready to be disturbed in a pathological manner.

THERAPY

The knowledge of those unfavorable circumstances is of great therapeutic value. Each of them *per se* may be sufficient to produce the disorder, but some of them may be at work conjointly. The largest majority of them and many others which are not included in the present study but which also belong to the group of facilitating factors of epileptic seizures, may be greatly decreased, combatted, or even suppressed by means of appropriate physiochemical measures. Gross therapeutics consisting exclusively of administration of drugs will not give desirable results and if continued the epileptic patient will remain their slave all his life. In every case of epilepsy one must always bear in mind first the special inherent epileptic predilection and second the easy convulsive reaction to all disturbing factors such as are being considered in the present report. The suppression of the facilitating factors is particularly efficacious in the early phases of the disease. Consequently early intervention is of paramount importance and upon the character of the latter the patient's future depends.

In all cases of essential epilepsy one must endeavor to trace all possible circumstances, that are apt to facilitate epileptic outbreaks on the order of those enumerated in the two hundred cases of the present series; one must analyze them from every standpoint, physiological, biological, chemical and physical, always bearing in mind that we are dealing with brains which possess a special reactivity of their cortex. The latter is observed even in the traumatic cases with cerebral lesions. In a previous study (5) attention was called to the striking fact that with identical cranial injuries resulting in identical cerebral lesions a trauma may in a certain group of cases be accompanied or followed by epileptic seizures, and in another group be totally free from such manifestations. In the traumatic cases therefore we are bound to admit that a lesion of the brain becomes epileptogenous only when there are also other factors at work, and that the role of these factors is to produce a cerebral irritation on the basis of physical or biochemical influence. In the present state of our knowledge while waiting for a true pathogenesis of epilepsy, therapeutic resources become per force limited to tracing and combatting conditions and circumstances, facilitating outbreaks of convulsive seizures, such as presented in this study.

TABLE	No. Cases
a. Dyspeptic manifestations in a normal gastro-intestinal tract	40

The Use of Sedatives, Tonics, Endocrines, Etc., in the Reëducational Training Treatment of the Epileptic

L. PIERCE CLARK, M.D.
New York

We shall take up for consideration the favorable influence of sedatives which may be combined with the phases of reëducational training treatment, psychic and physical, that have been laid down for the epileptic. In many instances if one fails to reach and remove the cause of the disease, sedatives judiciously administered may find a fitting use, either temporarily or for periods of years.

For the subject who gains a sense of relief after one of his long interval periodic convulsions, no effort should be made to unduly check their occurrence beyond a point of safety. In fact large doses of sedatives in such subjects are contraindicated. Even in epileptics who have many attacks it is often best not to attempt to abolish them altogether. A relative cure in epilepsy is frequently an honorable aim. So long as the patient is none the worse for a seizure now and then, or when an actual attack is a decided asset, he may be allowed to have one without using methods for suppression. A chronic inhibition of attacks often gives rise to a cumulative outcome, and the character of the case may be changed from a relatively benign to a severe or malignant type.

With the advent of more rational systems of medicine within the past fifty years some decided improvements in the use of drugs in epilepsy have been attained. It seems to have become generally conceded that the general specific therapy of the disorder rests upon the selection of a sedative principle of medication.

This, however, may be seriously combatted by the actual clinical evidence brought forward. Looked at in a narrow sense, the seizure epoch is an explosive discharge; but when we recognize that the fit itself is but the terminal process of a long sequence of antecedent causes, it is impractical in the extreme to repress the latter. Even if we base a sedative therapy upon the theory that the disease is dependent upon the rate of metabolism or oxygen consumption in the nerve cells, and that its effectiveness is really a chemic one acting upon a cortical defect in chemic dynamics, the situation is by no means much improved, for we have not a single shred of evidence as to the normal physiology underlying mentation. The final representation is that as a residual of the attacks (symptomatic pathology) there is a variant lesion of the cortex, the loss of whose elements to any destructive degree is unrenewable; hence we may not look for any system of natural restoration of parts such as may be the case in many other structures of the body, but there is simply an overgrowth of neuroglial elements, a scar replacement at best. Viewing the disorder in such a fatalistic light, the wonder is that any epileptics are cured or that seizures are brought to an arrest; yet grave exhibitions of the disease are often spontaneously terminated. In some instances the disease is outgrown in children and youths, and occasionally cases respond promptly to the specific therapy of sedatives.

In no disease, perhaps, is the removal of the seeming cause attended by so little permanent results. This fact alone shows that dependence cannot be placed upon such alleged causes. Rarely some source of reflex irritation may be recognized and removed with more or less benefit. Such advantages are largely attained in the earlier stages of the seizure epoch.

In the proper management of the use of drugs in epilepsy, one is to avoid everything that smacks of routine treatment. No doubt many of the failures in using drugs as directed against the seizure-frequency is due, first, to the fact that a rigorous plan is often not undertaken until the seizure epoch has become firmly established, and, secondly, that the individual patient is given too little accessory attention due to the seizure phenomenon engrossing the whole picture. The mere administration of a much recommended drug without studying the epileptic upon whom it is to be used will do little good and may work detrimentally in so many ways that it may destroy both the patient's and the relatives' confidence in any and all drug administration.

All sedatives, while perhaps having their maximum effect upon the neuromuscular and cortical apparatus *per se,* have a depressing effect upon the cerebral blood pressure; the heart action is also depressed as well as the whole vasomotor tonus. These drawbacks to sedation can be overcome in part by administering coincidentally vascular tonics and stimulants. Lastly —but ranking first in importance—is the host of gastrointestinal ills in many epileptics by nature and made much worse by sedatives.

Drugs are administered for the purpose of influencing the attacks, either by arresting their occurrence, or, failing in this, by rendering them less frequent and severe. We are still ignorant of any means of suddenly curing the essential disease, and from what we now know of its etiology and pathology it seems unlikely that any means of rapid or sudden cure will be forthcoming. Some types of convulsions which are less fundamental than genuine epileptic attacks are capable of early eradication in some instances.

Almost every drug in the pharmacopœia has done duty as a cure for the disease some time or other. The question is no longer between bromides and some other drug, but between drugs and drugless treatment. The influence of drugs is transient, which makes it necessary to make a repeated renewal. Since their introduction by Laycock seventy-five years ago the salts of bromine have enjoyed steady favor as antiepileptic remedies, notwithstanding the fact that they fall far short of meeting the important indications. The action on the human economy of all the bromide salts is essentially the same. Bromide of potassium—which is the universal remedy—acts as a distinct motor depressant, and coincidentally lessens the activity of the intellectual centres. Pushed to an extreme degree it produces apathy, listlessness, lack of interest, a dull, apathetic expression, and, if carried still further, produces a mental condition not unlike that of primary dementia or stuporous melancholia—a condition from which the patient usually makes good recovery when the drug is withdrawn. If pushed too far, death may supervene from acute bromide poisoning. Bromide also exerts a sedative action on the spinal cord, and thus lessens reflex excitability. On the circulation it causes, at first, a fall in arterial pressure. If given in toxic doses, it arrests the heart in diastole, while its long continued use results in a weakened and irritable condition of that organ and a general impairment of the circulation. In ordinary doses, it produces but little effect on the respiration; but in larger doses it acts as a depressant. It often impairs digestion, as it irritates the mucous membrane of the alimentary canal and interferes with the reflex activity of the stomach in a way to check the normal secretion of gastric juice. It causes constipation, a heavy coating of the tongue, and foul breath. It leaves a bad taste and a pasty feeling in the mouth, and causes loss of appetite and not infrequently nausea and diarrhea. It lessens metabolic changes through depressing the nervous system. It produces an unsteady gait, myasthenia, particularly noticeable in the legs; depression, and often loss of sexual vigor; forgetfulness and slight degree of aphasia, usually shown in the misuse of words and wrong formation of sentences. On the temperature, in ordinary doses, it lowers the heat of the body by depressing the heart action and possibly by contracting the arteries, a fact apparently established through the experiments of Brown-Sequard, Mairet, and Armory. The effect of bromide on the skin in causing acne is universally known. It is eliminated from the system very slowly and escapes unchanged.

In spite of their enormous drawbacks the general utility of the bromides—especially those of the sodium, ammonium and potassium compounds—may be attested to by the fact that they have held sway for over half a century. They are the chief ingredients of nearly all patent medicine mixtures. The average dose is from twenty to thirty grains of one of the salts or all three combined, three times a day, and little is gained therapeutically in modifications or adjustments of the dosage. What is seemingly required is that a more or less permanent daily amount shall be ingested. The clinical data upon which the drug amount may be based is the length of interval that exists between attacks, the time of day they usually occur, and the patient's general tolerance of the bromide. As a matter of practical value one may at times throw the attack into different periods of the day by giving the maximum of bromide dosage just before the expected time of seizure. Many physicians adopt the daily variation of bromide with a steplike increase of dosage for several days before the expected attack. This is usually as futile a procedure as that of a sudden induction of bromism at the outset of treatment, the character of which is too well known to the experienced therapist for detailment here. In point of fact the induction of bromism to any marked degree or extent of time almost invariably does harm. Above all, the proper functioning of the gastrointestinal and circulatory apparatus is absolutely essential. If one is intent upon high dosage of bromide the proper attention may do away with its often superficial defects by observing a plan of precaution which I have employed (1). The principle of high dosage of bromide may be looked upon as a form of hyperbromidism, bromide intoxication, or poisoning. The drug is given in a steadily increasing dose, as that of iodide in specific disease. The patient has high rectal irrigations once or twice daily to reduce the amount of congestive catarrh, to eliminate toxins induced by faulty metabolism or deficient oxidation, and for its diuretic effect. The patient is also given prolonged hot packs and baths at night for diaphoretic effect, and cold douches, sprays, and cold drip sheet treatment mornings to stimulate the peripheral sensory nerves and to preserve vasomotor tone. Vigorous deep massage is steadily maintained to cleanse the muscular circulation. The inordinate tendency to local stasis of circulation in the skin and its consequent depression of the skin function shown in acne, etc., is corrected by face packs, hot moist bran applications, and mild stimulation of ointment applied at night. Mouth and nasal cleanliness, occasional lavage of the stomach and large quantities of aerated vichy (two or three quarts daily) are absolutely necessary. Incipient heart failure may be gauged by the second pulmonic sound and the degree of splitting of the second tone. The latter is easily controlled by strychnine and digitalis. The food is always light, highly nutritious but not too concentrated; no meats are allowed. Bromides are generally given in plenty of water or vichy. Of recent years sodium bromide or triple bromides made into an effervescent tablet fulfills the latter requirement very well. If one is depending upon the bromide to induce a permanent arrest of attacks, its steady administration is necessary for at least two years after the last attack before it may be safely discontinued. Even then a gradual withdrawal is necessary covering a period of another year at least. But cures by the bromide treatment are usually not to be expected. If the fits are not con-

trolled by 60 grains a day, the question arises whether the epilepsy or the bromide is the greater evil. It is of frequent experience to see patients go months without fits but with a loss of mental and physical activity due to the medication. Among the ill effects of the bromides may be seen irritability, melancholia, bad temper, suicidal or homicidal tendencies, and temporary delusions. The secret of obtaining successful action with the bromides lies in the judicious method of their administration, and in carefully selecting each case for their use.

A salt free diet, inconvenient to maintain though it may be, is of value in epileptics as they are able to take smaller doses of bromide with the same efficacy as higher doses without manifest bromism. It is claimed that those taking the salt poor diet use a part of the sodium of the sodium bromide to replace the sodium of the decreased sodium chlorine in the bodily economy; thus perhaps a more fixed and stable combination of the medication is held in the tissue. Sodium bromide is not only quite palatable, but it is also cheap and is not inferior to any of the synthetic products.

As an emergency prescription, the following has been prescribed:

Potassium bromide	grs.	LX
Chloral hydrate	grs.	XX
Morphia sulphate	grs.	⅛
Tinct opii deod	M.	IV

Aqua ad. q. s. fiat Z j.

In psychic epilepsy, or in the psychic epileptic equivalent, the emergency prescription is generally not effective; the psychomotor violence in the latter is too great to respond to the bromides alone. In various forms of epileptic mania they are practically of little value, and the same is true of their use in most of the epilepsies due to recent trauma. Here they are actually harmful before the operation as they suppress important phenomena which may indicate the seat of the lesion. After an operation, and in longstanding traumatic conditions, they are more admissible.

The idiopathic grand mal epileptic of vigorous constitution and good digestion is the type of patient who does best under the continuous use of the bromides. The size of the initial dose must be regulated by the character of the fit and by the manner in which the drug is given; beyond the third or fourth year, age has but little to do with it. In most cases it should be given to the point of toleration or to the point required to control the attacks. This can be determined only after trial. Hypodermic use of the bromide salts is rarely called for. It is occasionally employed in status epilepticus, and usually causes abscess and a scar.

Notwithstanding the length of time that we have known the bromides to lessen the tendency to spontaneous discharges, we have no precise knowledge of the method of their action. That they act in consequence of the presence of the element bromine there can be no doubt. Bromide is said to cause contraction of the small vessels; but if it has this effect, it is not likely that its influence on seizures is thus produced. Bromides may be considered important in their efficacy in suppressing attacks, for thus free intervals are obtained and time is given for more tedious but more lasting forms of treatment to become of permanent service.

It is unnecessary to enumerate the various drugs that have been used in epilepsy. They are legion, and include codeine, borax, chloral hydrate, amylene hydrate, nitroglycerin, zinc, solanum carolinense, simulo, trional, chloroform, and the coal tar derivatives.

The general use of luminal in epilepsy has been only a matter of several years. Adverse reports of its insidious effects in producing physical and mental deterioration have been made. On the other hand many report the most signal good effects from its use. The latter are so enthusiastic as to acclaim it the most outstanding feature in the advancement of the treatment of epilepsy in recent years. Epileptics who do poorly on bromides are often amenable, for a time at least, to the action of luminal; this advantage coupled with the absence of the usual bromism which follows the prolonged or excessive use of bromide, makes it a popular remedy with the physician as well as the patient who desires to keep the nature of his disorder a secret. In an extensive experience with the drug I have known but two cases radically helped by its administration. The dose ranged from three fourths to two and a half grains daily in divided doses or one single dose at night on retiring. The marked hypnogogic effect of the drug somewhat hinders its administration by day. More extended and carefully controlled experience of the effects of this drug are needed to finally establish its place in our epileptic armamentorium, but present studies would seem to point that luminal will not displace the bromides in their deserved first place in treatment. Neither remedy is a habit forming drug. In case of recurrence of attacks after a prolonged free interval the epileptic is often intractable to a renewed administration of either drug, but careful analysis usually shows that the mishap is really not due to the inefficacy of the renewed use of sedatives which are again called for but rather to the progression of the disease, or some intercurrent mishap which at least enlarges and deepens the clinical significance of the disorder. The sudden withdrawal of sedatives for one reason or another often entails a series of attacks or status itself.

To what end are the practical plans of treatment of the epileptic directed? Underlying all of them is the principle that the epileptic and not his seizures is to be treated. What is really aimed at is, first, to adjust the epileptic to a well ordered simple life to which he can easily adapt physically and mentally. Now bromides and sedatives lower the epileptic's resistance to difficult adaptations. His whole motorial and sensorial responses are made more difficult for him.

To this extent the sedatives are harmful. Why, then, are they still so generally used? Perhaps the physician really hopes to reach the proper degree of sedation to take off the overstress, physical and mental, without paralyzing the patient's adaptability to his environment. But unfortunately this cannot be done, and in most cases the sedatives are sooner or later discarded. How, then, may a mental stability be obtained for the irritable, egoistic, selfcentred and supersensitive epileptic? We are again thrown back upon a strict analysis of the patient's peculiar makeup and its instinctive demands.

(*To be continued*)

Comments on Pedophilia

ERNEST E. HADLEY, M.D.
Washington, D. C.

"He who recalls an object that has once charmed him desires to possess it again, and under the same circumstances." SPINOZA.

Pedophilia, if defined as an abnormally accentuated fondness for children, occasions no profound negative reactions. Nothing is more usual than a frank and open affection for children. But when one reads of a brutal sexual attack on a child, the mind is filled with horror, or as may be. For this manifestation of exaggerated pedophilia, pity is extended to the unfortunate child, punishment is meted out to the unfortunate perpetrator of the deed, and mankind goes on loving children as is their natural bent, right and proper. Children require love and affection, with adult guidance by example. Adults need the love and affection of little children. We cannot here undertake an ethical-moral disquisition on the facts that a lack of love in one instance, or a too sensuous expression in another may exert unusual baneful influences on the child.

The granting of a somewhat general fondness for children paves the way for the presentation of some material, brought up during the analytical investigations of a patient, bordering on the pathological. The patient is a male of twenty-five years, a student of a graduate school. The rather extensive dreams, associations and explanations occasioned thereby, as relates to the problem as a whole, may be omitted. Suffice it to say that the major problem concerned emotional fluctuations, a partial impotence and an ejaculatio precox, with a correspondingly unsatisfactory social adjustment. The experiential data relating to the pedophilia may be collated, as follows:

The patient's mother prolonged his nursing period to an age from which he retained conscious impressions of the weaning process. Against this, he reacted with all the energy of which he was capable. Unsuccessful in his attempt to retain a method of gratification so satisfactory to his perceived needs, there was an outpouring of blind rage and hate toward all who seemed in any way in league against him. All the more sinister in that it was a futile powerless effort to destroy an unyielding system. Later on in life, this upsurging emotion of blind fury, rage and hate was reduplicated again and again when balked in some much desired procedure. But the child's love needs, vastly overstimulated by the prolonged and erotic union with the mother, were destined, by the very nature of the urge, to find some means of satisfaction. One may call it fate or chance, but very probably it was the exigencies of the situation which directed the child's attention to a neighbor girl of his own age. At any rate, unable longer to obtain any measure of love from the mother as he knew it, he directed to the girl what seemed almost insatiable cravings and satisfied them in practically the only way he knew how, after the fashion of the nursling he had not ceased to be, emotionally. It is probably of no little importance that the girl seemed as erotic as he. At any rate, a new experience was added to his fast accumulating methods of sexual expression. Whilst he first sought for her breasts and found them quite disappointingly immature, she with greater wisdom uncovered his genitalia and he, through the suggestion offered, we may suppose, by her behavior, sought for its analogy upon the body of his new love. Rising above the disappointment offered by her lack of a phallus, his desire to suckle led him to make use of what he found. Thus, the boy, by way of cunnilingus, found in the girl a direct substitute for the mother and undoubtedly the weaning, so far as the mother was concerned, seemed eminently successful. Too, we may assume, the girl by means of fellatio found satisfaction in the boy for similar motives inasmuch as together they for many months satisfied their cravings quite mutually. The patient had a very dim recollection of the exact circumstances surrounding the termination of the affair with this first little girl whose name he has not yet recalled. It is probable that she moved with her parents to another part of the city during the latter part of his fourth year. It must have been shortly thereafter that his next notable sexual experience began.

Quite frequently there came to visit at his home some people from a neighboring city. On such occasions these people, a man and a woman as he vaguely remembers and a little girl whom he clearly remembers, were obliged to, or at least did, remain at his home all night. This little girl, "Stella," and he were placed to sleep in the same bed. It was not long before the same mutual performance as with the first little girl occurred. Only here he remembers for the first time violent erections and a predominance of interest in what the little girl was doing to him. Other than the fact that the first little girl performed fellatio upon him, he recalls no particular interest in the act. But in this instance, with Stella, there was distinctly more interest in the oral manipulation of his penis by her than his own oral performance upon her genitals. On what was perhaps the last of a number of similar activities with Stella, he hurt her in some way with his erect and turgid organ in her mouth. In spite of the fact that her cries were sufficient to attract the attention of someone, probably the girl's mother, who so far as he knew strove in vain to ascertain the cause of her complaints, he felt no remorse for the distress he had caused her. On the other hand, he remembered quite vividly the lustful sensations occasioned. As he said, in recalling the incident, "I must have felt that I had really done something to her." Whether or not he had observed the father inflicting what might appear to be injury upon the mother remains unknown. Abundant references to pleasure in hurting small animals, especially pets, were ecphoriated and relate by sequence, association and analogy to this early exemplification of sadism with Stella.

The next few experiences which seem directly related to the phase under discussion deal largely with fantasies. On one occasion, it seems that a baby cousin was asleep with her genitals quite uncovered

in her bed when our patient espied her. For some time he lingered about the bed with a marked erection imagining how he would like to manipulate her. The probability of her crying out and attracting attention to him seems to have been the deterrent. Play activities with his girl cousins, of whom he had several his own age and younger, were so directed that he came as closely in contact with their genitalia as possible. He liked very much to carry them by placing them astride his clasped hands in such a manner that his hands came in contact with concealed parts. Frequently, he pinched and hurt them in his play. He sought every opportunity to see their pudenda and played roughly with them, as he says, so as to disarrange their clothing for this purpose. All of these things gave him a good deal of lustful gratification. Frequently, when there were no little girls with whom he could play, he would suck at various available parts of his own anatomy, imagining meanwhile that it represented a cunnus. A few attempts were made to perform fellatio upon himself, but without success. Somewhat later, he did play with one boy in mutual fellatio but this did not appear to have given him any particular measure of satisfaction by comparison with such experiences with little girls.

In his seventh or eighth year he became very much attached to a girl, by the name of Lucy, about his own age and on several occasions attempted to introduce his penis in her vagina, though without success. This followed attempts upon his part to perform cunnilingus upon her. She, it was, who directed him in the attempted coitus. Her persistence in the matter seems not to have gained her the expected pleasure since it appears their love affair was interrupted largely on account of the violence of his endeavors. The later attempts at coitus with Lucy were accompanied by a consuming anger and hate. In this connection it is interesting to note that of all the little girls with whom he played sexually in childhood, Lucy is the only one for whom he felt or retained an aversion.

In the experiences of the next few years there seems little to mention that concerns the present theme except masturbatory efforts with fantasies of being with little girls. During this period and the ensuing years to use his own words, he "fell in and out of love with girls on the slightest provocation." With a majority of these girls his erotic procedures were elaborated no further than in kissing, about the mouth and face.

About his twelfth year he became acquainted with a little girl named Anna who acceded to his request to play with him sexually. When first he performed cunnilingus upon her he encountered a previously unexperienced heightening of the lustful sensations. Quite beside himself with excitement, he then made a vigorous though unsuccessful attempt to effect a complete intromission. He was rewarded with his first ejaculatio and a degree of pleasure which he thought never afterward to have attained. The trauma to this little girl proved a barrier to further sexual activity with her, but the experience afforded food for fantasy to the exclusion of all other for some time to come.

In his sophomore year in High School he became enamoured with a girl little in physique but only three years his junior. He liked her very much and called to see her at every opportunity. She seemed to him to be the fulfilment of an ideal of purity and goodness which he was now endeavoring to foster. At the same time he was making a tentative examination of the theories of the church in an attempt to strengthen and fortify his anchorage in an ever widening and complex social system. To terminate our digression at this point I may say that the church failed miserably so far as our young sophist was concerned in offering any measure of solace to his urgent needs. To the little girl Evelyn he did turn with some degree of faith. But here again under cover of a shy, demure and saintly sweet external appearance throbbed a passionate being, which coupled with his faintly repressed passion led him into new ordeals of conflict. When the, to him, concealed emotion of Evelyn broke through the barriers and in a trice she stood before him partially disrobed, a palpitating savage, he was illy prepared for the storm of mixed emotions thereby stimulated. From somewhere, perhaps partially from the newer social strivings came the warning thoughts that here was a situation he must avoid. Evelyn, at any rate, had no such thoughts. The die was cast. The ensuing struggle left but little in memory of his actual emotions at that time. Whether he was struggling to get away from her, or struggling to accomplish the dictates of natural desire, or both at once, or what, is lost somehow in the confusion of the moment. That a wild struggle did occur and that therein he experienced an unexpected orgasm he had no doubt. And in the moment that followed, the desire emotions spent, he struck at her with unleased destructive passions as at a vile and venomous thing.

LATER YEARS

In the next few years, alternating periods of intense intellectual pursuits during which he was seclusive, thoughtful and unpassionate and periods in which he was gay, lively, sociable, hypomanic, intrigued for the moment with the charm of some particular girl, characterized his attempts to find himself and the key which would unlock the doors of happiness. His premeditated attempts at sexual intercourse were unsatisfactory. At the moment of contact with the prostitute he suffered a precocious ejaculation or failed entirely to develop an erection. With the girls of his social acquaintance, he either suffered an orgasm in the forepleasure rites, or if actually won sexually, he became quite impotent. It followed that periods of intense application to study lengthened and he completed a collegiate course with a major in philosophy. The period following his graduation left him stranded. He attempted various occupational pursuits from the clerical to the farm. He did not find any pleasure in work nor did he seem adapted to the work he undertook. Depressed and dissatisfied with his situation, he entertained fleeting thoughts of suicide. More often he entertained schemes involving wholesale destruction of the social system or planned on devising some new social superstructure in which he and a select few assistants would be more or less omnipotent. While he recognized his everchanging fantasies as such, that did not diminish the pleasure of the moment. Finally he decided to return to the University for graduate study and passed a very pleasant year. During this

year he lived alone and devoted all of his time to study.

In the beginning of his second year he lived with his sister, several years his senior, and her family, who came to live in this city. The sister had three children, all girls, three, five and seven years of age, respectively. At the same time he had occasion to meet a small "sickly" girl who lived in an adjoining apartment. This girl attracted him and he began paying her attentions which were gratefully accepted. In spite of her, to him, obvious unsuitability for marriage, because of her apparent ill health, he proposed and was accepted. During this period he became more and more restless in his sister's home. This situation became acute when a growing interest in his little nieces began to evidence definitely pathological traits. At first, occasionally, then more frequently, he became tormented with a desire to see their genitalia, to kiss them and to perform sexually upon them. Rather adroitly he found ways in which he might be left with the children while the sister made calls, or went shopping. His studies kept him at home and "it would be no trouble." Again, he reenacted the rough play activities and the tricks of his own childhood with little girls until he obtained a view of their genitals and could kiss them furtively on such parts without its seeming to be unnatural (as he thought) to them. Now, it was, that his impotence vanished. He enjoyed almost unceasing erections when with them so that masturbation satiated him only after several repetitions. Then one day he sat the little niece astride his turgid penis and permitted her to play horsey in a new way. The resultant orgasm seemed to restore his confidence in his potency and he began anew to develop interest in girls of his age. No further overt acts were consummated with little girls but he began to have thoughts of raping them violently and then disposing of their bodies in some fashion. A persistent recurrence of such ideas alarmed him and he contemplated leaving his sister's home. Little girls he saw on the street became the object of his colorful fantasies. One day he picked up a little girl on the street. She was lost or had wandered away from her home. He petted her until she stopped her crying and told her name. Without harming her in any way, he restored her to an anxious parent with some slight feeling of confusion in answering questions as to where he had found her, how he had learned where she lived, etc. In order to satisfy his inordinate desires he began a systematic attempt with girls of easy virtue. Here again his potency failed him at the crucial moment or the unsatisfying premature ejaculation occurred. In this condition he was referred to me for treatment.

DATA

The lifting of certain facts out of their perspective gives a onesided view of the personality of our patient. But since here, we are not concerned with his virtues—virtue for that matter being an idea which lends itself to grave distortion about as often as there are individuals who suppose they possess it—the events above related if not fully descriptive yet admit of consideration from an analytic standpoint. In this discussion it seems unnecessary to point out that the clarification of the entire problem of pedophilia cannot be made upon the basis of the material presented, or for that matter on any one case. If, however, some thought may be activated toward a subject none too prominent in our literature, the effort will have achieved its purpose.

The overvaluation of preadolescent cravings, which had served hitherto as an effective barrier to heterosexual function in our patient, was buttressed upon the prolongation of the mother-infant relationship. While our data includes no reliable information regarding the mother's behavior to the child, other than this prolongation of the nursing period, such later attention was given to his adult comforts as would permit speculating an early erotic interest in him. One cannot but wish that some statements might be secured from the mother as to how she rationalized the delay in his nutritional education. There was an elder sister, so, at least, we may assume that it did not result from inexperience. It too seems but reasonable to suppose that the mother did not find his manipulations of her nipple particularly painful, even after the eruption of several of the patient's teeth.

Not to digress upon warped pleasure taking on the part of the mother, we may emphasize the effect of such delayed weaning upon the partition between sucking as a step toward the satisfaction of nutritional needs and as in itself a pleasure source. Abraham (1) says that:

"An intense pleasure in the act of sucking is a feature of infancy. We have familiarized ourselves with the view that this pleasure is not to be ascribed entirely to the process of taking food, but that it is conditioned in a high degree by the significance of the mouth as an erotogenic zone.

"This primitive way of obtaining pleasure is never completely abandoned by human beings; on the contrary, it persists under all kinds of disguises during the whole of life, and even experiences reenforcement at times in particular circumstances. Nevertheless, the growth of the child, both physically and mentally, involves a far reaching renunciation of the original pleasure in sucking. Now observation shows that every renunciation of pleasure only takes place by way of exchange. It is just that process of renunciation and the course it takes under different conditions which merits our attention."

Sullivan (2), in his discussion of the oral complex, holds that in sucking "—chemical necessity is the proximate cause," but the "—neuromuscular patterns are prearranged. The sensory impressions from the tactile equipment of the lips leads to protrusion and the sucking of any suitable object brought into contact." While this may not appear at first glance to be entirely explanatory of the facts in our case, it is to be noted that the boy sought the girl's nipple and found it disappointing. Her prompt recourse to his penis may be assumed to have reminded him of its relative qualities, particularly its greater magnitude than the nipple that he had just uncovered. It is unfortunate that, as is so often the case, we cannot recover the mental processes he actually experienced on observing that the phallus was lacking on the little girl. Suffice it that he found something to suck, and this while he was being sucked—functioning in the mother rôle. The relation of this to psychical hermaphroditism will be emphasized later.

Environmental factors which supplied the little girl for the further satisfaction of the sucking impulse permits a linking up of the primary and secondary

objects—mother and little girl—and provides an explanation of later pedophilic interests in the incest urge. The erection of a physical barrier to the continuation of mouth-nipple union with the mother, added to the alleged instinctual incest barrier, makes possible an investiture of interest in the little girl of overshadowing symbol importance. The relegation of the primary love-object to a position of apparent insignificance is more or less in keeping with the usual process of psychosexual evolution. However, in this instance, there occurs a direction of the love impulse, with slight modification in its method of satisfaction, to an object so sufficiently opposite as to carry a minimum of similarity to the first. While the sucking continues for a time still to be merely sucking, the object is not only no longer a superior but an equal or inferior, and the use of the new object includes the important factor of her physical act to and on him. One might ponder, in passing, on the relation of her act, by analogous thinking, to kissing by his mother. The point I emphasize in confirmation, as I see it, of the view of Abraham is that our patient at the instance of weaning has in the renunciation of love for the mother merely made an exchange of objects.

From the viewpoint of this sucking impulse one may see in his later behavior during childhood and the chronologically adult period almost a compulsion to repeat an experience of such cherished import. This desire to repeat an experience, to repossess an object or an object substitute as near like the one which so erotically charmed him in childhood is of particular significance to the understanding of the pedophilia. While this inordinate fondness for little children, this pedophilia, in the chronologically adult person might preferably be interpreted as a regressive mechanism, it seems clumsy to refer to regression when the libidinous tendencies have not proceeded to higher biologic aims. The senile, tabetic, paretic, sclerotic, etc., who resort to pedophilia, may fit more appropriately in the category of regressive behavior. Bleuler (3), who presumes that pedophilia "occurs perhaps most frequently as an acquired anomaly in senile dementia," notes that "it is not rare also among imbeciles, *faute de mieux*." My own contact with the literature does not bear out the idea that pedophilia occurs most frequently in the senile. Bloch (4) considers pedophilia as "a very widely diffused phenomenon." He goes on to say that, "It arises from superstitious grounds; as, for example, from the belief which prevails in many countries that venereal diseases are cured by copulation with an intact child. The primeval belief that intercourse with immature girls prolonged life, that an emanation from them rejuvenated old men (the socalled "Shunammitism"), led in former times, and leads even at the present day to acts of fornication with children. Less commonly do timidity and impotence on the part of adult men, rendering intercourse with adult woman difficult or impossible, give rise to seduction or rape of defenseless and unsuspicious children."

In connection with the comments of Bloch upon the relation of pedophilia to superstition, I have made corroborative observations upon the American negroes among whom there exists a rather widespread belief that gonorrhea may be cured by sexual relations with little girls. Bloch adds a footnote from a report in the *Archives for Criminal Anthropology* (16: 173, 1904) concerning "a peasant affected with venereal ulcers," who, "having been advised that a cure could only be obtained by intercourse with a pure virgin, had sexual relations with his own daughter and—was cured!!" Experience in pediatric clinics gives ample evidence in the shape of venereal infection on the prevalence of such superstition among the ignorant, even today.

While Shunammitism, or rejuvenation by means of intercourse with immature girls, failed miserably with King David (v. I *Kings* 1, 1-4); that is to say, when the girl was brought before the dying king, he "begat no heat," showed no signs of potency, we do see quite clearly how successfully the potency of our otherwise impotent patient was restored when brought into contact with the little girls. The whole theory of Shunammitism seems based upon the existence of a pedophilia.

Sullivan, in a forthcoming study on sexual evolution, insists upon the factor of convenience in explaining some of these cases. To him, the adolescent male seeks an object not so much for love—which at this time must be of great "purity"—but for the satisfaction of crude sexual impulses. Bestiality is to such an one, if of any cultural developments, less attractive than the use of a human. Only prostitutes, who are horrible because of the incest barrier, and children and youths are available. Whether girls—who are apt to be considered difficult to approach, or boys shall be his objects, is determined by his previous experience. If circumstance offers children—those well below the level of his development—and less troubled by those scruples which he has developed—they are peculiarly apt for his purpose.

Pfister (5) reports a case of pedophilia in a youth of twenty-three whose reaction to this condition was: "It is much easier to rape a child."

While we do not deny the face value of opportunity, fear of impregnation, failures in repression through organic alteration, etc., these considerations do not alter the fact that this method of sexual expression relates to a stage in psychosexual evolution, which, were the truth known, might be shown to be a dominant force throughout life.

Laurent, as quoted by Bloch, dramatically described a "burning out" process in speaking of "debauchees" and "exhausted roues." He writes: "They have used and misused woman; they have explored all the stages of natural and unnatural love; they have visited Lesbos and Paphos; and they have experienced every possible sexual artificiality. Their sexual desires have become torpid, their manliness is on the decline, and sexual death approaches. But the more exhausted they are, the less willing are they patiently to acquiesce in their loss. It is with them as with inebriates who are full to the throat and still continue to drink. One day they notice a little girl in the street and feel stimulated by her youthful charms. Thus, their love begins." Perhaps it would be better to say that, in so far as the adult is concerned, a manifestation of pedophilia becomes evident.

The impulse gains expression, and in our patient appears to spring from the autoerotic period of childhood. The little girl was subjectified as a part of his

pleasure world. The object was to please himself, and here in the case of the little girl no conquest was necessary. She existed for his own benefit. His later masturbation, interest in little girls and those of easy virtue may be seen as a reflection from this period where his desires were so easily gratified. Again, in that later period when the existing social system demanded behavior more in keeping with biologic aims, we see the element of annihilation in phantasy of all that stood between him and the fulfilment of his desires. This emotional reaction of hate toward society is easily seen as a replica of that uprushing of hate toward the mother which occurred on the institution of weaning. The purer sadistic fantasies of forcibly raping little girls and killing them may be seen as an extension of the lustful sensations achieved on hurting the little girl, Stella. But killing little girls, because of the fusion of the mother symbol with the little girl symbol may also have been the desire to destroy the incest craving. Further evidence of sadism which seems to exist in his striking the girl, Evelyn, who had so suddenly become repellent to him, is of interest in the light of the incest motive. Stekel (6) presents two interesting case reports. One, an artist of sixty-two who becoming potent after the death of his wife, brutally attacked a servant who had infantile sexual organs, after which he paid her and thereafter satisfied his awakened interest with his young students. It appears his impotency was a defense mechanism. He dared not become potent lest he murder his wife. The other report concerned a village schoolteacher of twenty-six whose impotence, as brought out by an abundance of dream analyses, involved a religious complex and was a moral defense against his sadism. The sadism took origin from his youngest sister for whom he had a marked pedophilic and incidently incestuous craving. In speaking of the pedophilia in the aged, this author is inclined to the belief that it originates in the love of one's own youth and is a backward direction through narcisism to the infantile state of the sexual impulse. The aged one desires to fulfill his pathological wish before he makes his exit off the stage of life.

Narcisism, as displayed by our patient, seems to have belonged more nearly to the autoerotic phase of love of himself rather than to its extension in the homosexual phase of someone like himself. His inclinations clinging ever to a mutually erotic and satisfactory situation with a little girl was irritated only by the inimical social system and the promptings of the biological law of recreative procreation which he transgressed. One must keep clearly in mind in dealing with pedophilia the distinction between that mediating homosexuality, and the more pure perversion which is our subject.

A nice question concerning the significance of cunnilingus is raised in this case by his later elaboration of the performance to include the insertion of his tongue in the vagina. A double rôle of the aggressive male may perhaps be seen in the later mutual affairs with little girls. The girl is, indeed, the passive agent and his bisexual component in two senses. Mutual fellatio with the little boy may further illustrate an hermaphroditism, where he plays the rôle of passive female and aggressive male. It is one of the most regrettable things that, because of the interruption of this analytic investigation, more data on this solitary event could not be secured. Weighty factors must certainly have had their effect to destroy his satisfaction in this procedure, to isolate it from repetition. One may wonder if he had assimilated fellatio entirely into his complex of the female, so that on the one hand to perform it himself was too feminine, and to be directed to the more adult coitus too far from his adopted route of gratification with the female as shown by his later impotence. The affair with Lucy is especially emphatic in connection with this hermaphroditism and the striving to masculine activity. Failing signally to satisfy her demand for the more adult coitus, he directed to her a hate which survived for years, a hate which cannot but be a loathing of a dimly realized inadequacy.

There appears to be a prevailing belief that homosexuals seldom, if ever, resort to pedophilia of the type under discussion. This is readily understood when homosexuality is considered higher in the scale of psychosexual evolution. Pedophilia as here understood does not relate to an expression of love towards the adolescent youth, as in the Grecian period, but rather toward little children. One of the philosophers of that cultural epoch, although accepting heterosexual love as divine, propagated the idea of a stud farm and recognized in youth a more exalted expression of love, partly from the idea of giving without return. As in those days intellectual pursuits are ofttimes the bridge transporting youth through adolescence to manhood, but the intensity of the early strivings of our patient were only temporarily displaced by his student activities. Practically, however, it acted effectively in that manner sometimes understood as sublimation.

However extensive a discussion of pedophilia might be, it would be inadequate were nothing said concerning its opposite, though not exact antithesis, the misopedia. Hate toward children is observed in so many little disguises in everyday life that its occurrence in the popular sense is interpreted by the average mother as "cattiness," being "selfcentred," "interferes with their parties," *et cetra, et cetra.* Extensions of misopedia are often observed in unwarranted irritation; complaints about their behavior, their touching and upsetting things; remarks such as "they ought to be whipped—or made to mind" and certain advice to others as to "How to raise children." Such disguised forms of misopedia may be interpreted as a defense mechanism against erotic cravings.

Note may be made of the case in which one's child may by a process of identification be a too potent reminder of their own autoerotism. This is an even more regrettable result of such defense, than the prevalent mishandling of the children's sexual problems by parents. It actually seems in some cases this defensive lack of frankness, stirring unpleasant affect because it is dimly appreciated, is projected as an actual misopedia. Antagonism to an unborn child has been quite clearly brought out in my work as an unwillingness to accept the responsibilities of motherhood, an antagonism to the husband, disinclination to accept the pregnancy as not to have been the result of a father impregnation fantasy, or its rejection because it represents the "reward of sin." In our patient, the description of whose pedophilia we have presented, the desire to kill the object of his affection seems to have been rooted in a terrorizing fear of the

incest craving. Oppenheim (7), whose article on misopedia is the only available treatise on the subject that I have at the moment of writing, finds in each of his five cases a disharmony between the husband and wife, and a morbid background from which he infers that the hatred directed toward the child may have existed prior to its birth. He points out, however, that the hatred may have arisen from the mother-daughter conflict, especially since, of the five cases reported, in each of which a child was killed by its mother, four were female children.

[1]Since this article was written, information has been received from a reliable source to the effect that the individual, the subject of the above communication, has been making a satisfactory adjustment. This is of especial interest in view of the fact that the analytical study was prematurely interrupted. There are these rare instances in which a partial insight is sufficient to give such impetus to the outflowing libido that object investiture of a more adult order is obtained.

In the interval following upon the termination of treatment in this case, this individual—formerly one dominated by his early fixation in such fashion as to motivate him to deplorable conduct—has entered into the heterosexual stage of libido development and is the father of a son, six months old.

The Treatment of the Psychoneuroses by the Removal of Focal Infection

E. C. DUDLEY, M.D.
Chicago

I make no claim as a psychoneurologist. The chief purpose of this paper is to invite discussion. At the outset permit me to quote two distinguished physicians whose intemperate language doubtless was due to the heat of discussion; one is a neurologist of deserved eminence, the other a dental and oral surgeon of international fame. One is reported to have said that "anyone who removes a colon for insanity is criminal"; the other went a step further and is reported as saying that the managers of the State Hospital for the Insane at Trenton, New Jersey, "are themselves insane." Such comments more or less mollified or intensified have been so widely broadcast by men whose opinions we must respect that one is forced to ask the question how far, if at all, these opinions are merely casual and indeterminate. Why does a profession usually openminded and keen for new and useful ideas condemn these pioneers in the treatment of the insane by the removal of focal infections and at the same time accept similar treatment for so many other disorders? Why this singular exception to a law which following the epoch making work of Billings, Rosenow and Gilmer has become classic? The reason is not remote; it obviously is a protest against the many disappointing results arising from surgical operations performed upon insane patients without just regard to indication, to purpose or to effect. The colon, for example, was recognized by former enthusiasts as the cesspool of the body and as such given undue importance. Then followed in quick succession numerous operations, sometimes with scant regard for anatomical, diagnostic or pathological indications. Some of the results were deplorable. Worst of all was the sidetracking of the colon, an operation devised to avoid the more dangerous colectomy. This procedure, now relegated to the dark ages of abdominal surgery, united the lower ileum to the lower colon and threw the remaining large bowel out of circulation, leaving it a quagmire in the abdominal cavity. All this and more goes to explain the antagonistic attitude especially and justly toward the older protagonists of colonic surgery. The question now is, how far a judicial examination of defocalization at the present time will justify the criticism.

History appears to repeat itself. Witness McDowell, the first ovariotomist, characterized in a medical journal of Philadelphia as an irresponsible Kentucky backwoodsman. In France as an audacious American, by an Edinborough editor as a reckless adventurer; this editor on his knees finally asked forgiveness of Almighty God and of Ephraim McDowell. The early ovariotomists were stigmatized as "belly rippers." Scarcely a generation ago some men were anathematized as public enemies who ought not to be at large because they advocate appendectomy. Fifty years ago as a young intern I assisted a deservedly recognized surgeon of New York in numerous ovariotomies, with one hundred per cent. of mortality. The abdominal cavity even then was a *terra incognita.*

It is amusing yet instructive to look back not so long ago on the withering scorn with which the old family doctor replied to his humble patient who told him that he had a cold or a sore throat which had "settled in my knee or my back." This was of course focal infection and serves to illustrate how the common people through the ages have descried and foreshadowed great discoveries which ultimately the scientific world was compelled to recognize. Now there is evidence that much of what has been regarded as essentially brain or nerve disease turns out to be disease in distant organs. This is quite analogous to delirium in typhoid fever in a person of otherwise normal brain.

I confess that only a short time ago I looked upon colectomy and other defocalizing measures as questionable procedures, rarely indicated and of doubtful value in the treatment of the psychoneuroses, but intemperate criticism sometimes strengthens a cause

and so one day I found myself impaled on the horns of a dilemma and perplexed over the question, a crucial question. Why have we thus favorably generalized on focal infection in its relation to other disorders with the sole exception of the psychoneuroses? Is it possible that any considerable proportion of these cases may have otherwise normal or nearly normal brains and nervous systems overburdened with infection from distant organs? Does the analogy hold with focal infection as a cause, for example, of arthritis, myocarditis and nephritis? Supplemental to this perplexing situation came the startling statement that the State Hospital for the Insane at Trenton had saved the state an approximate two million dollars in six years by its pioneer work in the treatment of the insane by the removal of focal infections. This saving is said to have been effected by the discharge of patients who otherwise would have remained a charge upon the state under the old custodial care. I went to Trenton where the medical director gave me *carte blanche* and personal conduct to every department.

I saw two total colectomies, for the removal of megacolons singularly alike in pathology. There were strictures at various points with corresponding extreme dilatations, the bowel wall being attenuated to the thinness of thin paper which thus would open the way for the transudation of fluids and gasses directly into the peritoneum. Apparently in parts the mucous and muscular coats were so atrophied as to leave little protective bowel wall, except the peritoneum. There were numerous pigmented patches indicating advanced degenerative changes. The glands in the adjacent mesentery were greatly enlarged, evidently by infection from the colon. Later in one private case I saw a megacolon, recently removed, nearly seven feet long with a sharp elbow kink between the ascending and transverse colon, with old adhesions to the duodenum and with all the above described pathology much exaggerated. Professor James Ewing, of Cornell University, on examination of this colon in my presence pronounced it to be one of the two most extreme specimens of pathological colonic changes he had ever seen, a colon which could not have performed its function for years.

PERSONAL CASES

I recall numerous cases in my own practice which on opening the abdomen gave forth a strong fecal odor which raised the question whether I had not accidentally opened the bowel. All these were doubtless cases in which transudation of gas had taken place through the attenuated bowel. A condition hitherto not recognized.

From my relations with the asylums and prisons of Illinois, as former President of the Board of Commissioners of Public Welfare, I am not unaware of the difficulties and discouragements, both legislative and professional, in securing equipment and finding qualified experts for such highly technical and special departments as laryngology, rhinology, x ray, bacteriology and especially oral genitourinary and abdominal surgery. It was gratifying to find much evidence of satisfactory equipment and efficiency in these departments.

The case records and followup reports would do credit to any general hospital. There was an abundance of illustrative pathological specimens, all classified and arranged for systematic study of morbid anatomy, including hundreds of colons, many of them megacolons with excessive pouching. In one specimen there was pouching of the pelvic colon to a diameter of not less than ten inches.

TRENTON HOSPITAL

Whatever the final verdict of the value of defocalization among the insane, it is certain that the history of focal infection never can be written without taking into account the work of the Trenton Hospital.

There are now available for study in the Trenton Hospital and in the private practice of members of its staff more than five hundred cases of colectomy and thousands of cases of minor defocalizations in other organs, surely a sufficient number upon which to form some sort of general idea of the value of these important procedures as a factor in the treatment of the psychoneuroses.

In colectomies alone I have seen enough pathology to indicate that the work is being done under diagnostic and pathological indications. I can only account for the recorded arrests and symptomatic relief from manic depression, epilepsy, dementia precox and other disorders on the hypothesis of unusual surgical judgment and technic. These impressions are strengthened by verbal reports of patients and members of their families.

In the well equipped and modern laboratory of the State Hospital, scrupulous care has been taken in the study of the post operative pathology. This study has also been aided by the McClintock Memorial Laboratory of New York.

The classification of insanity roughly falls under two groups: I, the organic group in which there are organic lesions of the brain; II, the functional group, also designated as the surgical group, in which presumably no significant anatomical brain lesions are present. This is an indefinite classification, since in many cases lesions may be unrecognizable even postmortem under the microscope and yet we cannot prove that they are not present. Clearly the functional cases would furnish the material for the surgical group. Since the characteristics of both groups may combine in many cases there are manifest difficulties in making a clear scientific definition of either group, but for practical purposes it is not difficult to exclude many cases from the surgical group, such as diabetics, alcoholics, victims of senile dementia and syphilitics. Nor is it difficult by exact diagnostic measures such as x ray to select promising cases for defocalization.

At Trenton only cases which on x ray, including the barium test, show positive colonic surgical indications are recognized as suitable for colectomy. I do not know the exact percentage but it is quite appreciable and is said to be increasing with improved diagnostic study.

The mortality of colectomy has been discouragingly high. In one series of 169 cases at the State Hospital it averaged thirty-one per cent. I understand that this mortality has been reduced in twenty-six cases, by improved technic, to sixteen per cent. This gives reason for hope that it may finally be reduced to the plane of the other more serious abdominal operations.

REPORT

Very significant is the report of Commissioner Lewis which he kindly sent me in the form of a personal letter.

State of New Jersey
DEPARTMENT OF INSTITUTIONS AND AGENCIES
December 17, 1925.

Dear Doctor Dudley:

I have your request for information relative to the economic results attributable to surgical defocalization and other medical treatments at the New Jersey State Hospital for the Insane at Trenton. Previous to 1918, under custodial care, free patients were a charge upon the State each for an average period of about fifteen years at a cost to the State of approximately $372.00 per capita per year.

About thirty-six per cent of the functional cases were discharged annually previous to 1918. This closely approximates the proportion of discharges then and now in other states. Since 1918 the number of annual discharges of functional cases has increased to over sixty per cent. A reasonable explanation of this increase could be attributed to surgical detoxication and other medical treatment. The savings are further increased by a reduction in the number of new buildings required and by medical follow up work with discharged patients. In the seven years, 1918-1925, the increased number of discharged patients who thereby ceased to be a charge upon the State have brought about a saving of over a million and one half dollars. Taken year by year through 1923 these savings appear on our records as follows:

1919	$ 31,174.00
1920	106,420.00
1921	243,588.00
1922	438,601.00
1923	692,437.00
*Total	$1,512,220.00

Should you wish to go minutely into the subject all our statistics and records are at your disposal. It is a far cry from the time when the insane were possessed of the Devil and were treated as we would treat the Devil if we could get hold of him. For example there was a statute in the State of New York authorizing the authorities to chain the insane whenever they got their hands on them.

Very truly yours,
(Signed) Burdette T. Lewis,
Commissioner.

*In a conversation with me Mr. Lewis states that the saving in 1914 will bring the total to an approximate $2,000,000.00.

I append the following statistical review taken from recently compiled records of the hospital and furnished to me by the medical director.

Two series, each of five hundred consecutive cases, have been studied, on the suggestion, as I am informed, of Professor Adolf Meyer of Johns Hopkins University, to determine results five years after admission. The first series embraced the old custodial methods, as in vogue, 1908-11, the second series was composed of patients treated by the modern methods of defocalization and admitted 1918-20. The treatment referred to consisted in the elimination of focal infection in the teeth, tonsils, gastrointestinal and genitourinary tracts.

These two series showed the following results at the end of five years:

First Series

Recovered	*Discharged unimproved*	*Died*	*Remaining in Hospital*
140	37	67	256

Second Series

Recovered	*Discharged unimproved*	*Died*	*Remaining in Hospital*
328	27	65	80

The most striking fact shown relates to the number of cases remaining as a charge upon the State. Of the custodial group there were 256, or fifty-one per cent., still in the hospital at the end of five years: of the defocalized group there remained only eighty, or sixteen per cent. These statistics explain the saving to taxpayers referred to in State Commissioner Lewis's letter. These statistics are now for the first time published.

It would be remarkable and exceptional indeed, if in the vast amount of new ground which has been broken and the diversified work which has been done there had not been some mistakes of judgment, some over enthusiastic claims, some inadvertent exaggeration of results based upon *post hoc non propter hoc reasoning*. On this subject I have no adequate data on which to deny or affirm, but this is not very pertinent to the subject, for such errors could hardly be so gross as materially to modify the results as reported.

I confess that I still retain some lingering courage of my prejudices. We want to know whether the Trenton Hospital is opening the way to a new departure in the treatment of the insane, I mean defocalization, in consequence of which any considerable number of the insane may be not merely improved but at least symptomatically relieved and returned to their homes as acceptable members of society. I refer to people who otherwise would remain for life under that classical custodial care which pertains to many asylums for the insane. Very long and very painful is the evolution of an idea.

If the claims for defocalization cannot be refuted they will have to stand. Clearly an unprejudiced nonpartisan discussion is in order. Judgment on *ex parte* testimony is not permissible; it outrages a fundamental principle in scientific morality.

Assuming that the figures of Commissioner Lewis are approximately correct for the two fifths of the insane of the State of New Jersey cared for in the Trenton Hospital, and basing an estimate on the population of the State of New York which according to the census of 1920 was more than three times that of the State of New Jersey. This does not take into account possible detoxication in suitable cases of the criminal insane, which might increase the saving materially. To this end it is herewith suggested that a new hospital for the surgical work of the insane be established near the city of New York where experts in the various departments would be available. This might very materially cut down the enormous appropriations now contemplated for the insane hospitals of the State and might well become an object lesson for the other states.

Respiratory Paralysis.—D. C. Elliott (*American Journal of Surgery*, Vol. XXXIX, No. 10) finds that some toxic reactions may follow caudal anesthesia either immediately or delayed, judging from our knowledge of two such reactions in a series of six hundred cases. Acute novocain poisoning may follow the puncture of the dura mater and the intraspinal injection of the solution or the absorption of the novocain into the systemic venous system, through the puncture of a large vertebral vein, and thence into the external iliac veins.

In spite of these possible dangers we believe that caudal anesthesia is relatively a most valuable form of regional technic and is a suitable and satisfactory procedure in various surgical, gynecological and obstetrical procedures. The procedure can be made more safe by the addition of a prophylactic dose of caffein sodium benozate into the solution injected as is done in intraspinal anesthesia.

Neurosis and Total Personality*

FRANZ ALEXANDER, M.D.

Berlin

When we consider the development of our views on psychoneurotic affections in a wide perspective, the line of this development may be characterized by the fact that we are coming more and more to regard the disease as the expression of the totality of the person. I should be doing our science an injustice if I did not, at the outset, ascribe this endeavor to it. However, the latest theoretical works of Freud denote an advance in this direction and have contributed essentially to the comprehension of the psychic phenomena of disease in all of their relations to the total personality. The criticism of these works even in psychoanalytic circles is not uniform, but I find the usual designation *speculation* to be wholly inappropriate. The reconstruction of the structure of the psychic apparatus as undertaken by Freud proceeds forcefully from the empirical material of analyses of neuroses and is continually confirmed anew by experience if one applies it to the individual case, and it shows us the way to investigate the finer structure of this apparatus.

One might also characterize the direction of development of psychoanalysis as follows: while at the outset our interest was directed in the first line to repressed content, to the expressions of repressed desires, we gradually occupied ourselves more and more with the nature of the repressing agency, with the motives and laws of repression. Somewhat crudely, although meeting with the essentials, we may say: in the beginning we learned about repression, while today we are to grasp the conception of the repressing agents. At first we had to learn the language of the unconscious in its material significance, and now we seek to understand its grammar and syntax. The formulation that at first we studied the libido and later the ego, is not entirely appropriate, because the repressing factor itself places the libido at its service. Think only of the moral masochism: we have to do here in the first place not with qualities but with differences of direction. One might say while the expressions of the repressed are centrifugal, the expressions of the repressing agencies are centripetal. Hence the expressions of the suppressed libido are violent, visible, while the working out of the suppression dynamically directed inwardly is invisible, and often merely inferred by deduction. So that that part of our science which investigates this field is not speculative and at most must often employ deduction proceeding from empirical facts. It is, however, no more speculative than the atomic doctrine which forms ideas of the structure of matter without being able to observe directly.

One obtains the impression that investigation of the repression is associated with still greater difficulties—we may and must express it as still greater resistance—than is the repressed content of the soul. This resistance is manifested only in this way, that the expressions of the libido were also formerly understood chronologically, although, especially in the hours of treatment, should the unconscious want of punishment be touched by the characteristic expression of the repressing agency, the cause of this particularly great resistance is obvious. We have long known that the neurotic symptom is the consequence of a miscarried repression, and that guilty of this miscarriage is the repressing instance itself. The remarks of Freud on the intimate relations of the superego to the *it* condense themselves in our performances to the complaint that in the neuroses the superego has entered into a secret alliance with the *it*. That by the superego the repressing agent is meant, need not be discussed further here—this is clearly apparent from the text of Freud's writings according to which the superego is the repressing instance, which was set up for the repression of the Œdipus complex. In the neuroses it fulfils its task insufficiently, it cannot deny its origin from the *it*, it often decrees cruel punishments and yet it is unable to prevent that the unmodified expressions of the *it* come to expression much more powerfully than in normal subjects. One obtains the indubitable impression that it is exactly through this punishment, through suffering, that the neurotic acquires the right to hold fast to the tendencies which are foreign to the ego. Be this as it may, in the neurotic personality equilibrium has been displaced in the direction of the repressed, the unadulterated *it* has preserved a high efficacy although its expressions are restricted to the fantasy life and to symptom formation. We will for this alteration first draw the repressing agency itself to responsibility. From this consideration it follows forcefully that it does not suffice to unmask the secret sense of the symptoms; rather are the neuroses attacked in the citadel by the treatment only when the mechanism of the symptom formation is discovered, when that psychic association becomes known which makes possible the formation of the symptoms. I would like to call this the economic analysis of the total personality. Only the unmasking of the secret alliance between the suppressed and the suppressing tendencies can lift up the neurosis from the ground. At this place is hidden the key to the amplification of the efficacy of our therapy. And on this account this place, as the last inmost zone of resistance, is the most difficult to occupy. It allows a glimpse into the most intimate unofficial headquarters of the *it* and of the responsible agency to that impulse which of necessity it must renounce. Its official headquarters are now known. The neurosis is felt as a disease from which the patient would now be freed. That this is not the most intimate viewpoint of the total personality is shown by the tenacity with which the symptom is retained.

I would like to illuminate these relations with a picture of political life, in which the relations of the individual psyche recur in a microscopic enlargement. The excesses, the illegal action of a party of extremists hostile to the government are not so interesting for the inner political criticism of a country

*Read before the IX International Psychoanalytic Congress, at Homburg, September 3, 1925.

as the question how such actions are possible with the official refusal of the responsible party leader. The suspicion of a secret understanding between the refractory members and the party rulers awakens, and only the unmasking of this secret teamwork can bring to a head the deepseated change in the relations.

Before I begin my discourse of accusation against the repressing agency in the rôle of neurosis genesis, I must endeavor to characterize it with the utmost truth. Our well founded knowledge of the process of repression allows me to be quite brief. With two criteria I have said the most important facts on the suppressing agency. This repressing is an unconscious process and hence its laws are likewise unconscious, deviating from the viewpoint of the conscious personality. We also know of conscious inhibitory processes and in contrast to unconscious repression we use such terms as condemnation, oppression, renunciation, etc. The difference between the laws of the repressing agency and the conscious ego come to expression most distinctly in that in general more is repressed than would come into consciousness. Think only of the most characteristic example, that of sexual repression. With incest endeavors the total sexuality, even that directed to the exogamous object, is clogged. The cause of this summary overrepression lies in the genesis of the repressing agency, the formation of which goes back to earliest youth and corresponds to the psychic relations of the child at that period. As the repressing instance gradually solidifies, becomes automatic and loses ever more the connection with the outer world, I have shown in my paper before the Salzburg Congress.

I named it an introjected code of past time which like every code is conservative. While the conscious ego develops itself further, makes itself free from sexual restrictions and also from infantile objects, the repression agency, especially the neurotically diseased, maintains the atmosphere of childhood against the sexual claims, still always with the old prohibitions, the old spirit, and thus rescues a fragment of the past.

From this character description of the repressing agency which in its nature is doubtless identical with the superego, we can yet derive no secret favor of the repressed tendencies. Its derivation from the Œdipus complex makes it indeed suspicious, although a former criminal may make a good police officer. We could hitherto at the most reproach the superego with a certain conservatism, although with no sordid secret motive favoring neurosis. From these characters can be derived at most an inhibited, overmoral character, although not the manifold symptoms of a neurosis with all its ways of suffering. And yet in these qualities the superego already contains the germ of a neurosis formation. This conservative overstrictness of the superego has burdensome internal political consequences for the soul.

When we observe the structure of a neurosis the connection strikes us that exists between selfpunishment tendencies and the condemned, ego foreign wishes. This connection is so apparent that it has been known from the first, even if the economic regularity hidden behind it was not yet grasped. One actually gets the impression that the symbolic or other disguise of a repressed tendency did not yet suffice that this, in the form of a symbol, was purged away, but it must at the same time correspond to the need of punishment. As a matter of fact we see that the symptom often has a double sense—a selfpunishing and an ego foreign, impulsive sense.

We know how to express it in the interest of simplicity that the symptom is just and superego just. In other cases the two opposed tendencies are subdivided into two or more connected and simultaneously existing symptoms. The scope of my address today does not permit me to go into details. I have in the Berlin Psychoanalytic Institute sought to present these relationships in a series of lectures on the individual forms of neurosis. Without adducing individual examples it suffices if I recall to you the structure of the compulsive neuroses or manic depressive conditions in which these relationships are most distinctly visible. I have compared the psyche of the compulsive neurotic with a certain merchant who carefully enters all his debts and claims and is mindful that both sides of his bookkeeping are always in equilibrium. So the compulsive neurotic takes care that the symptoms with masochistic selfpunishment content always holds the balance to the sadistic, ego foreign expressions. On the other hand he utilizes every plus in self punishment, in sufferings thereto in order to be able to discharge himself on the costs without punishment and sadistically. Often he compulsively makes the right hand make good for the criminality of the bad left hand.

Freud's comprehension of the connection between the manic and depressive periods is known to all. The terror of the superego, its rage against the ego proper, follows the revolutionary suspension of the manic period, the tyrants of the superego in the melancholic serve for the justification of the excesses in the mania.

In hysteria the expression of the need of punishment is not always so clear in the individual symptoms and still less so in the total behavior of the patient. We must not forget the chief criterion of the neurotic symptom that it indicates suffering. Suffering is the general denominator with which the claims of conscience are made equal, as Freud specified at the Berlin Congress.

This is the point from which the nature of the disease is first made intelligible. A neurosis is a disease and disease indicates suffering. We must not lose ourselves in the analysis of the individual symptoms and thereby forget the human being as a whole. This error we must leave to our colleagues the internists. Every expression of the female hysterical stands in the service of announcing suffering. Her entire noisy histrionics serve to reveal her suffering to her environment. And this officious announcement of her suffering is only the discharge of unconscious feelings of guilt. The greater the sense of guilt the graver must be the symptoms of suffering. And the more the hysterical suffers, the greater the claim she makes upon her entourage. She has reckoned up her duties with suffering, she has only more to demand. The preanalytic physician, like the naive entourage, has intuitively sensed this direction of the neurosis and named it an imaginary disease. This meant that the neurotic suffers with sufficient (more correctly without visible) cause, herself procures the disease.

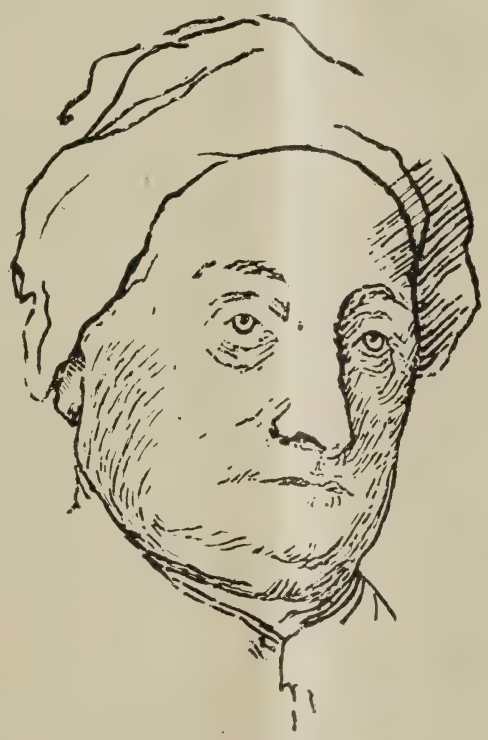
Historical Medicine

Contributors to Medical Science

Hans Sloane

It has been said that in Great Britain, at any rate, the lives of three physicians, Sydenham, Sir Hans Sloane and Heberden, completely bridge over the uncertain period between old empiricism and modern medical science. The career of Sydenham has been sketched in this series and after the main incidents of Sloane's life have been narrated, the same service will be done for Heberden. Sloane, the seventh and youngest son of Alexander Sloane, receiver general of taxes for the County of Down, before and after the Civil War, and a commissioner of array, after the restoration of Charles II, was born at Killeleagh in 1660. An Irishman by birth and a Scotsman by descent, he exhibited in no ordinary degree the thrift, energy, pleasing manners and address of natives of these respective countries.



SIR HANS SLOANE

From the earliest years the bent of his genius was towards the knowledge of nature and this leaning was encouraged by education. He chose medicine as a profession and in order to gain a good knowledge of its several branches went to London. He studied assiduously anatomy, botany and chemistry. His aptitude for natural history brought him into touch with Boyle and Ray, to whom he communicated every curious or useful observation which he made. Having spent four years in London, he went to Paris, attended the hospitals, heard the lectures of Tournefort the botanist, of Du Verney the anatomist, and other eminent teachers. Having obtained letters of introduction from Tournefort, he went to Montpelier, and was introduced by M. Chirac, then chancellor and a professor at that university, to all the learned men of the province. He spent a year in collecting plants in the district and traveled through Languedoc with the same end in view.

In 1684 he returned to London, intending to settle there and follow his profession. He gave Ray a great variety of plants and seeds which Ray described in his *Historia Plantarum.* At about this time Sloane became acquainted with Sydenham, who took him into his house and introduced him to all his friends.

On January 21, 1685, he was elected a Fellow of the Royal Society and on April 12, 1687, he became a Fellow of the College of Physicians. But his tastes were rather in the direction of natural history than active medical practice, or he was averse from settling down, and he gladly accepted the offer of the Duke of Albemarle, then Governor of Jamaica, to accompany him there as personal physician. He remained in Jamaica fifteen months, and made a collection of the flora and fauna of the island. On the death of the Duke, Sloane came back to England with the Duchess, arriving in London in July, 1689. From that time on he remained in London, applied himself closely to his profession, and his professional career, social position, and scientific reputation became alike brilliant. In 1694 he was chosen physician of Christ's Hospital, a post he held up to 1730.

In 1693 he was elected secretary to the Royal Society and immediately revived the publication of *Philosophical Transactions,* which had not been issued for some time. He continued to be editor of them up to 1712, and the volumes, which were published during this period, contained many of his contributions. In 1701 he was made M.D. of Oxford University. In 1705 he was elected a Fellow of the College of Physicians of Edinburgh, and in 1708 he was made a Fellow of the Royal Academy of Sciences of Paris. Four years later he was elected a member of the Royal Society of Berlin. In 1719 he became president of the College of Physicians, and in 1727, on the death of Sir Isaac Newton, he became president of the Royal Society and was appointed physician to George II. In addition to these honors he won the distinction of being the first medical practitioner to be made a baronet. In 1742 Sloane left his residence in Bloomsbury and in the society of his library, museum and a select number of scientific friends spent the last years of his life at Chelsea, the manor of which parish he had purchased in 1722. He was then eighty.

It may be mentioned that in his youth he was extremely delicate, manifesting symptoms of tuberculosis, but by careful living he attained the age of ninety, without, as an old chronicler says, even feeling the infirmities of old age. After a short illness of three days, he died on January 11, 1752, in his ninety-first year. Although said to be extremely

penurious in his latter years, he was a liberal benefactor to the poor. He was a governor of every hospital in and about London, to each he gave a hundred pounds in his lifetime and at his death a more considerable sum. He sketched the plan of a dispensary, where the poor might be furnished with proper medicine at cost price. This plan, with the assistance of the College of Physicians, was afterwards carried into effect. He gave the company of the apothecaries the freedom of his botanical gardens in Chelsea. He did all in his power to forward the establishment of the colony in Georgia in 1732, of the Foundling Hospital in 1739, and drew up the plan for bringing up the children.

He was the first in England to introduce into general practice the use of Peruvian bark as cinchona was termed in those days, and in the words of a chronicle of the period used it "not only in fevers, but in a variety of other distempers, particularly in nervous disorders, in mortifications and in violent hemorrhages." But the fame of Sir Hans Sloane will rest mainly on his contributions to the knowledge of natural history. He was, perhaps, the greatest of English naturalists and his collection of natural specimens of every description was remarkable. He bequeathed these to the public, on the condition that the sum of £20,000 should be paid to his family, which sum, it is said, was not nearly half of the original cost, and scarcely more than the intrinsic value of the gold and silver medals, the ores and precious stones contained in the collection. There was also a library of more than fifty thousand volumes; 347 of which were illustrated with cuts, finely engraved and colored from nature. Three thousand five hundred and sixty-six manuscripts, and a very large number of rare and curious books. As said before, this museum and library passed into the hands of the nation for a comparatively small sum, and became the nucleus of the British Museum.

Pope, the greatest poet of the time in which Sir Hans Sloane lived, refers to Sloane in his moral essays:

> Tis strange the miser should his cares employ
> To gain those riches he can n'er enjoy;
> It is less strange the prodigal should waste
> His wealth, to purchase what he n'er can taste?
> Not for himself he sees, or hears, or eats,
> Artists must chuse his pictures, music, meats;
> He buys for Topham drawings and designs,
> For Pembroke statues, dirty gods, and coins;
> Rare monkish manuscripts for Hearne alone
> And books for Mead, and butterflies for Sloane.

J. Cordy Jeafferson in his interesting and amusing *Book About Doctors* tells this tale of Hans Sloane and Handel, the great composer:

"The most abstemious of eminent physicians was Sir Hans Sloane, the president of the Royal Society of the College of Physicians and the founder of the British Museum. A love of money, in his old age, made him a hater of all good things, except money and his museum. He gave up his winter soirées in Bloomsbury Square, in order to save his tea and bread and butter. At one of these scientific entertainments Handel offended the scientific baronet deeply by laying a buttered muffin on one of his books. "To be sure it was a gareless trick" said the composer in his broken English when telling the story. "but it tid no monsdrous mischief; pode it but the old poogvorm treadfully oud of sorts. I offered my best apologies, bud the old miser would not have done with it. If it had been a biscuit it would not have maddered; but muffin and pudder. And I have said, Ach, mine Gott that is the rub, it is the pudder! Now, mine worthy friend, Sir Hans Sloane, you have a nodable excuse, you may save your doast and pudder, and lay it to that unfeeling gormandizing German; and den I knows it will add something to your life by sparing your burse."

But if Sir Hans Sloane was in his old age inclined to somewhat extreme thriftiness it may be said that he "pinched and saved" in order that he might be magnificently generous publicly. As a scientist in an age when science was only beginning to emerge from the obscurity of ignorance he shone with bright light, and by founding the British Museum he not only was a benefactor to the British nation but to the entire world. Sloane will live as one of the great British scientific medical men.

John Locke, philosopher and physician, was a contemporary of Sir Hans Sloane, and that at one time he was in active practice is proved by one of the many letters which he wrote to the medical baronet.

"Dear Sir.

"I have a patient here sick of the fever at this season. It seems not violent; but I am told 'tis a sort that is not easily thrown off. I desire to know of you what your fevers in town are, and what methods you find most successful in them? I shall be obliged by your favor if you will give me a word or two by tomorrow's post, and direct it to me, to be left at Mr. Harrison's in the 'Crown' at Harlow. I am, Sir,

"Your most humble servant,
"John Locke."

Harvey, Sydenham, Locke, Sloane and Heberden were all of the same era. Harvey and Sydenham were contemporaries although Harvey was much the older. Sydenham, Locke, Sloane were contemporaries while Sloane and Heberden were contemporaries. These were all great medical men. Harvey and Sydenham were great pioneers, Sloane less so but more scientific than Sydenham, and Heberden, perhaps, in a lower category than Sloane. Locke was not known as a famous physician but was perhaps the first of English philosophers.

Femoral Hernia.—L. F. Watson (*American Journal of Surgery*, Vol. XXXIX, 12) concludes that the inguinal operation for femoral hernia has the following advantages over the femoral route: It gives a good view of the sac and contents; the constriction is quickly located and easily divided; an abnormal obturator artery is easily seen if present; there is more room to deal with the intestine, and resection or anastomosis, if necessary, can be carried out easily and without traction on the loops; and it also permits inspection of the intestine at a distance from the ring beyond the point of constriction.

One of the serious objections to the inguinal operation in strangulated hernia is the reduction of the more or less contaminated contents of the sac into the abdominal cavity. The inguinal incision opens Hesselbach's triangle, consequently there is always danger of a postoperative direct inguinal hernia, which is more difficult of cure than the original femoral hernia. The inguinal operation is more difficult and requires more time than operation by the femoral route. It is more troublesome in males, on account of the obstruction of the cord, than in females. In these subjects difficulty is usually encountered in suturing the conjoined tendon to Cooper's ligament.

Maimonides' Treatise on Poisons

LOUIS J. BRAGMAN, M.D.
Syracuse, N. Y.

(*Concluded from page* 107)

All the previously mentioned foods are very good also for the bite of a mad dog, with the exception of salt, of which only a little should be put in the food. The broth of young hens is specific, as well as good fowls such as turtle dove, partridge, and mountain hen; avoid young pigeons, however, for they are bad. Cabbage is especially good for dog bites, and also cooked or uncooked onions and garlic, or fish, particularly salted ones, but not, however, daily; broth of river crawfish is very good; but all the foods are nourishing and curative, each through the specific property which God gave it. Acorns are also of value, and cooked they prove to be a good food. Above all, the brains of cooked hens are mentioned as being specific for stings or poisons; they are as conducive to health as broth of turtle doves, which clears up the condition through its specific power. Lemon peels are especially useful against all poisons, above all leaves of lemon trees drunk as a decoction.

All doctors agree that the fumigation with ram's oil drives away all poisonous animals, and especially snakes. They likewise maintain that the fumigation with goat's nails, mustard, sulphur, nigella, or opium, or scalp hair, each taken separately, drives snakes and other poisonous animals away by means of the smoke; by the fumigation with all the substances taken together even the scorpion is driven away. One should therefore take the initiative with these things, and fumigate the locality in which poisonous animals are situated; for the advantage of human intelligence lies in the precaution, the saving, and the reassurance against all plagues, which are liable to attack the body; although there is no truer security than the foresight of God.

SECTION II. CHAPTER 1. PROTECTION FROM DEADLY POISONS

In the opinion of the writer it is fitting to insert here a statement regarding a matter recognized by physicists, but not generally by physicians; and if Galen makes reference to this matter, he does it only as it pertains to medical science; he does, however, refrain from explaining that general statement which I now have in view.

We know that all substances which are composed of elements possess color, taste, and odor; all these are undoubtedly accidental; yet it is not with color as with odor and taste. The color is an accident of the coloration, and the perception of this accident is the same for every observer without distinction, so that, for example, in reference to black, one type of person cannot perceive the form of black, and another the form of white, but its effect is necessarily the same for every observer. Taste and smell, however, are not of the same quality, for one substance can have the most extreme sweetness for one, and the most extreme bitterness for another; for one class it may be sweet and pleasant, and that is the conception of sweetness; another cannot stand it, and becomes unpleasantly affected by it, and that is the conception of bitterness, or acridity, according to physical laws. People are aware that cantharides is very bitter; on the other hand swine enjoy it, and people think consequently that it does them good. So it is with different kinds of odors; namely, for one species an odor may be pleasant smelling, for another evil smelling; here again the pleasantness of smell and taste depend upon the nature of the individual.

Furthermore, some plants may be nourishing for one species but poisonous for another, just as Galen mentions, and of which he quotes examples. According to these facts, I have observed that every plant or animal substance which smells sweet and pleasant, is undoubtedly a suitable food and can be relished with confidence. What, on the other hand, is bitter, pungent, sour, etc., like those things which are nauseating, we do not relish until we have been convinced of their nature; for there is a pungent plant which may be taken for wild radish, yet is really a deadly poison; similarly, there is a plant which resembles the mushroom, inclines to be black in color, and is poisonous. We tend to be cautious of these various kinds of bad odors and tastes, and against everything of whose nature we are unaware. We must also be careful of colored foodstuffs which are in common use, such as thick broths or those into which lemons have been put; others containing unusual color, as for example, foods in which sumac or pomegranate juice or fish sauce has been cooked, or in which a sour, or an astringent, or an insipidly sweet taste predominates, or foods with a strong odor like those prepared with vinegar, in which there are onions, or which are flavored with garlic. We should eat these foods when they are freshly prepared, and when they are reliable in that nothing strange can be detected in them; for the ability of harming by poisoning through food, is feasible only when the taste or odor or appearance is unchanged and unrecognizable.

This is impossible by means of meat or fowl, which is merely cooked in water, or roasted, for the least thing that happens here causes the taste, or the appearance, or the consistency, or the odor to change. Also, no deception can be practiced in the case of pure water, for one guards against drinking unprotected water, in that poisonous animals often drink therefrom, and cause harm by means of the poison which they leave behind; I have often seen and heard of such cases myself. However, he who believes that he can prepare a deadly poison which has neither a strange odor nor a bad taste, the color in which it is thrown does not change, nor the quality of the substance itself, on account of the minute quantity which he uses, which is none the less lethal, especially if it be put in water or chicken broth—such a person who believes that he can accomplish this is far from knowing the art of therapeutics; yet this idea has received general acceptance. In reality, all that is poisonous

and harmful, no matter what it is, will have a bad taste or odor in proportion to its nature; for harmful things, even in minute quantity, are bound to change the appearance of that into which they have been placed. The wisdom of protection against poisoning by foods lies therefore in eating food prepared only by trustworthy hands. It is easy to put poison into wine, for this is especially adapted thereto, since in this instance the change in color, odor, or taste cannot be detected. Whoever then takes some knowing that he may be poisoned thereby had lost his ability of discrimination.

It seems to me that bread cannot be used as an aid in deception, however, one does not take any from those whom he suspects of a fraud, but only from those in whom he firmly trusts. It is far fetched and difficult for an evil minded person to put a poison in a simple food or drink, but with complex foods and drinks the trickery may succeed; if such an occurrence happens, while it may not kill, it can cause severe harm, and the deliverance therefrom rests in the hand of God.

CHAPTER 2. GENERAL RULES FOR THOSE WHO HAVE EITHER TAKEN OR BELIEVE THEY HAVE TAKEN POISON

Whoever has taken a deadly poison or fears that he has done so, must first induce vomiting by taking hot water in which anethum is warmed and into which much oil has been poured; the mixture will purify the stomach; after this a quantity of fresh milk must be taken, then immediately vomited; then after a while some butter and honey must be taken and vomited. It is said that chicken dung, by inducing vomiting, has a remarkable power of eliminating the poison; take two drams of it in hot water. Then eat the foods which have been mentioned with much bread and butter and honey; if the food has been digested in the stomach, it will induce vomiting, for oil, milk, and fat break up the malignity of the poison and protect the body thereby. After this one takes the remedies which are especially adapted for poisons, the simple or combined ones, depending on what is on hand; and if the substance has not left the stomach within eight hours, as was mentioned in the case of the bitten person, then the patient takes the foods detailed in the sixth chapter, observing the same regime, and preventing him from falling asleep, as mentioned, until his food is digested. If he is observed to improve, he can be allowed to sleep, and the same nourishment can be continued for two or three days, then he can be given one of the effective remedies, simple or combined. If the medicine had left the stomach, feed him young hen or cock, until he returns to normal. If in spite of all your prescriptions severe pain occurs in the stomach, or smarting, or diarrhea, then there are different remedies for this and for other complications which may make headway, but such are not to the purpose of this treatise.

CHAPTER 3. SIMPLE AND COMBINED REMEDIES FOR THOSE WHO HAVE TAKEN AN ESPECIALLY DEADLY POISON

Those simple or combined remedies which possess the specific power to counteract all poisons, without distinction, are called, in a phrase: "those remedies which are essentially useful for poisons," or life-savers, or also, bezoar, which is a Persian word. The best of all the combined remedies which help against deadly poisons is, as is well known, the large theriac, the mithriadic, then comes the theriac of four ingredients, under the simple term emerald, which is so well for those who have taken poison or have been bitten; it is a theriac which also possesses the specific power of strengthening the heart, if it is taken by mouth, and helps for the pain of the stomachache if it is applied over the stomach. Ibn Zohr mentions all these in his *Experiences,* and confirms them copiously; he was the greatest man to prove the value of these remedies, and the one who occupied himself mostly with them, and also the one who had the greatest talent in this regard on account of his great affluence and erudition in the art of therapeutics. All his scholars and associates who came to me told me that he never let himself be without a gold vessel containing the great theriac with a piece of emerald, for he was extremely apprehensive of being harmed by deadly poisons.

After the emerald comes the animal bezoar, then the essrog seeds, all of which have been already mentioned, as to dosage and method of taking. Other simple remedies are: silvestrene, two drams in wine; seeds of red silvestrene, or hydrangea, one siclus in wine. Also any kind of mentastrum one has on hand. If it is fresh, warm one ounce in one half litre of wine; if dry, powder and sift and take three drams in wine. Also all kinds of tripe, especially hare's, one half to one and one half drams, in a swallow of sour wine; these are antagonistic to all poisons. All are easily found and of great benefit.

CHAPTER 4. RULES FOR THOSE WHO KNOW WHAT THEY HAVE TAKEN

I have already remarked that I would mention those things that can easily be taken without the nature of their substance being known, that is, with which one can be easily deceived. To this group belongs ox blood, one of the deadly poisons, and one with which one can be easily deceived, if it is used to thicken a dish, or with cakes prepared from meat; it is a deadly poison. If one recognizes the poison as ox blood, vomit the food taken by means of tripe and warm sour wine, then vomit again by means of saltpeter and sour wine, then take kharub seeds, two drams, asafoetida, and borax, one dram. Take the latter as a powder with sour wine; if vomiting follows, it is just as well; if it remains in the stomach and passes through the bowels, it is even so just as good, and is restorative. Then eat one of the mentioned foods, avoiding those contraindicated in the previous chapter.

In the opinion of the writer, if the skilled physician considers the rules regarding the poison which is especially harmful and deceptive, he will not find the treatment difficult or embarrassing, particularly in reference to the mineral poisons, as martik, verdigris, and arsenic; if the odor of the poison is not easily recognized, then the color of the food will not be changed; and in addition, these poisons are very deadly. On the other hand, there are plant poisons, such as opium, which do not change the color, yet change the odor in a great degree. Others change neither odor nor appearance, as the milk (or fat) of lovage, and juice

of anacardium; but a few of them alter the taste recognizably. In connection with this feature, doctors find men in certain countries whose wives deceive them by means of a food, so that they die in a day or two, but what is worse than death, are sometimes afflicted with a suppurating leprosy; the prepared food causing the flesh to fall off. I have found many men in every city that I have visited who have encountered this, but the details which I have heard from others are more than can be mentioned here. I tell what the doctors themselves and their preceptors report: that they have investigated the circumstances with unusual pains, until they have learned that the food with which the wives deceived their husbands, was prepared with menstrual blood. They take the blood in the beginning of the period, even though it should be scant, and throw it into the food, and the suffering results. This, however, is not mentioned in the books which I have read, so that they do not contain a chapter for its cure. But those doctors have told me that they have saved many men from suffering, especially in the onset of the condition, by the above mentioned emetics, and have cured them with these simple and combined remedies, namely, borax, tripe, saltpeter, kharub seeds, fig tree ash, extract of mulberry leaves, drunk simply or together, according to the age. I have no experience in the matter; I hold myself obliged to mention only what I know of it, so that the information may be made known to others, and each may try what he sees fit.

It is advisable further, that he who wants to protect himself from all suspicious foods refrain from eating the foods himself, until a great proportion has been eaten by another, and it is not sufficient that it merely be swallowed, as I have seen the king's cook do in his presence.

One can also be deceived with schukran and bendsch; these are a species of hyocyamus. If one is cognizant of having taken some, heat the bark of the mulberry tree in vinegar, and take as an emetic, then take milk, and go through the procedures mentioned above.

Datura metel (stramonium), a sort of hermodactyl, is extremely poisonous in the weight of one siclus; but the cold Indian nut is much more so; it is said that it kills in a half a day with cold perspiration and cold breath; it is a poison which is commonly found, and with which one can easily be deceived, for it changes neither the taste nor the odor, hence is highly unnoticeable. If one is aware he has taken some, then saltpeter must promptly be taken as an emetic, and warm water and oil; then much butter, and much wine in which pepper and spices have been put.

Mandragin can be sucked out of a wound without harm; but its shell and grain are harmful. I have seen many women and children partake the same unknowingly with the customary symptoms of redness and swelling of the body, itching, and a sort of intoxication. Treatment is the same as for datura metel.

It is above all easy to be deceived with cantharides, but this can be recognized by the injury to the bladder and the hematuria, with stinging pain and evacuations, and death after a number of days. The cure is found in the second chapter of this section, which mentions the usual emetics, continuously drinking decoction of dry figs; then drink the juice of sileos and of purslane with sugar water and continue with the treatment until the inflammation subsides; finally, take as nourishment milk with bread and butter, as mentioned in the sixth chapter of the first section.

One may sometimes eat sponges and mushrooms, not recognizing the nature of the species; both of these are very harmful, and yet are eaten abundantly in the East and West. There is a deadly species of each, namely, the kind that is black or green or malodorous. But even the harmless kind may, on continuous eating, cause an angina, leading to death, or severe colic. Whoever eats this species, therefore, must add pepper and salt thereto, and much undiluted wine must be taken with it. If the deadly species is eaten, as soon as symptoms appear take a broth of goat's cheese in the proportion of one ounce to two drams, Indian salt, one half dram, and after they have been in the stomach a while, vomit them. Then drink oxymel with extract of radish leaves, and vomit; then drink small quantities of undiluted wine. Another source of accident of diet is a special kind of solanum (nightshade); the extract of which is often mentioned among those substances which are used in the diseases of the internal organs. The dark seeds of the black species are gathered; if these are taken in the form of a drink, severe angina immediately follows, then staggering, and hemoptysis; the cure consists of the aforementioned emetics, with the subsequent vomiting with water and honey; this latter is repeated almost constantly, until improvement.

This finishes what your servant considers sufficient according to the commission assigned to him; perhaps it will prove to be satisfactory; with the help of God, amen.

Calcium Chloride as a Diuretic and Its Influence Upon the Circulatory Mechanism.—Harold N. Segall and Paul D. White (*American Journal of the Medical Sciences,* November, 1925) say that in cases of cardiac failure with edema in which constant rest in bed, digitalization, and the administration of various diuretics have not resulted in a satisfactory diuresis, calcium chloride may be employed as a diuretic. No deleterious effects were observed from the oral administration of calcium chloride, ten to fifteen gm. a day, in any of the cases studied.

Editorial Articles

OUR EMERGENCY APPARATUS

Dr. H. B. Richardson describes, in the *Journal of Biological Chemistry,* some interesting studies of a case of congenital absence of sweat glands in a boy. The child got along very well without this apparatus except that he could not play as he wished during hot weather, though he had learned to make up for Nature's omission, on occasion, by wetting his shirt. The water vapor given off at rest was of normal amount and sufficient for ordinary loss of heat.

Various good offices for health have been attributed to sweating and, even when details of results are omitted, we are often urged to exercise daily to such a degree that the sweat glands will be brought into action. The inference is, either that our exercise should be sufficiently violent to bring this about in any season, or that we are purified by the elimination process. Of course it has long been known that the sweat glands were not essential organs of secretion, nor has there been any ground for the assertion that we need to exercise in so violent a fashion.

The sweating glands, as Dr. Richardson says, have been developed to supplement the ordinary evacuation of water through the skin and they constitute an emergency apparatus which becomes progressively less essential as conditions of life and survival become easier. The "sweat of our brows" is not necessary for the earning of a livelihood by a very large percentage of mankind.

If the exercise of the sweating apparatus is nonessential for health and longevity, we are not so certain that the exercise of the muscular system also is as essential as many persons suppose. For most this bulky machinery is now neither necessary, as it was with out ancestors, for escape from enemies nor for pursuit of food. There are many muscles which are barely used save in the pursuit of athletic pleasures and most of them are rarely brought to full development or action after our youthful days. In a word, it is highly questionable whether for health we need to exercise more than we are naturally inclined any more than we need to work our sweat glands systematically.

There is vastly more lung than most of us need to use at any time and there is no proof that we are actually the better for systematic deep breathing, at least so far as the lungs are concerned.

There are other physiological apparatus which also are intended for emergency purposes. The digestive system is capable of double the capacity of work in the active that is needful in persons at rest, and the liver and the kidneys are similarly built on the emergency plan. Unfortunately, these food handling mechanisms seem to be much more often used to excess and without need than are the muscles, lungs or sweat glands. Whether emergency use of these functions in ordinary conditions of life conduces to a harmful outcome we cannot say, though such might be expected to be the case, for in our distant ancestors feasts were not followed by feasts but by fasts and even in times of abundance there were neither cooking nor condiments to provoke to intake in excess of necessity. When it was needful that there should be abundant muscular work, the large alimentary activity was in evident harmony with the energy requirements, but for the modern sedentary person there is likely to be entirely too much stoking for the work the machine is to accomplish. It is no trouble at all for most of us to use the muscular, the respiratory, and the heat eliminating machinery with economy, but when it comes to the food handling apparatus there is another story and a story which does not seem to fit in with hygiene. Our feeding and food should be adjusted to body needs and if our hunger were consulted such would doubtless easily be the case, but when our it-tastes-so-good appetites hold sway (as they usually do) there is certainly lack of adjustment, to say the least on the subject. To take excess food and try to compensate for this by muscular exercise does not seem either a logical or physiologically economic procedure.

CANCER AND ITS TREATMENT

Several books concerning cancer have been published recently, some of them of a popular character. One of the latest and one of the most authoritative is by Dr. Charles P. Childe, Methuen and Co., Ltd., London, consulting surgeon, Royal Portsmouth Hospital and expresident of the British Medical Association. It is a practical book in which the author takes the view generally accepted that the only chance for successful treatment is early diagnosis and prompt surgical measures.

It is pointed out that cancer has no characteristic symptoms and that consequently the disease, especially in its earliest stages, cannot be diagnosed with certainty except by microscopic examination after operation. But he tells of the various danger signals that should make us suspicious of the coming of cancer and urges the public to consult a medical man as soon as such symptoms exhibit themselves. However, perhaps the main interest of this

book lies in Dr. Childe's views as to the causation of cancer. He holds that cancer has no relationship with diet and that chronic constipation or intestinal stasis is a negligible factor in its causation. In fact, in his opinion it is a local disease. Yet he voices the belief that while it is not a constitutional disease, it is a disease of civilization.

Mr. H. W. S. Wright, Kegan Paul, French Trubner and Co., London, E. P. Dutton and Co., New York, discourses on the conquest of cancer, which he deems feasible if an early diagnosis is made and operative methods done in time. He believes, with the majority, that chronic irritation is one, if not the most fertile, cause of cancer and advises that a persistent pimple or a small ulcer be excised without delay. Mr. Wright scoffs somewhat at intestinal stasis as a probable cause of cancer. On the other hand Dr. Leonard Williams, writing on *Middle Age and Old Age,* Humphrey Milford, Oxford University Press, stigmatizes intestinal stasis as the greatest enemy of civilization and he wholeheartedly agrees with those who state that cancer is a disease of civilization and that intestinal stasis brought about by overeating and unsuitable food is chiefly responsible for the prevalence of cancer.

There is practically universal agreement among members of the medical profession that, at present, the only effective means of treating cancer successfully known is by surgical measures undertaken in the early stages, in some instances greatly aided by irradiation. If cancer is a constitutional disease, and the testimony in this direction is stronger than in the direction of being of local origin, then the evidence in support of intestinal stasis as a cause cannot be overlooked. Chronic intestinal stasis will provide both foci of irritation and a suitable soil. Also if cancer is a disease of civilization as Dr. Childe thinks is probable, the constitutional theory of causation leads itself to the view more than to the local theory of origin. Those who are of the opinion that gastrointestinal troubles play a considerable part in causing cancer, teach that it is likely that the disease may be prevented by careful diet and mode of living generally.

As an example of the varying views which prevail with regard to cancer, the experiences of noted surgeons may be cited. Mr. James Sherren, surgeon to the London Hospital, in an address given before the Interstate Postgraduate Assembly of America held recently in London, stated that he had never seen carcinoma develop after gastrojejunostomy for a small mobile ulcer on the lesser curvature, although it was true that in at least a quarter of cancerous stomachs evidence of preceding simple ulcer could be found. Dr. Charles Mayo has recorded views of a similar kind.

Dr. J. H. Dible in the *British Journal of Surgery,* 1925, xii, 666, gives the results of an inquiry on the subject instituted by the Manchester Pathological Society. The conclusion arrived at was that transformation of a chronic gastric ulcer into a carcinoma is a possible but rare occurrence. Dr. H. Finsterer, *Wien. Klin. Woch.,* 1925, xxxviii, 295 and 321, holds directly opposite views. So strongly he believes that simple gastric ulcer may develop into carcinoma, that as the outcome of his long experience he thinks that wide resection in simple gastric ulcer is to be regarded as a prophylactic method against the occurrence of malignant disease. The situation with regard to cancer seems to be that early diagnosis and prompt operative measures coupled with the use in many cases of radium or x ray therapy are the only effective means of treating cancer.

It is possible, too, that preventive methods, dietetic and otherwise, may keep off cancer, by avoiding the establishment in the body of foci of irritation and by devitalizing the system and so decreasing the powers of resistance. Are certain persons more prone to malignant disease than others, and is there, to some extent, a cancer diathesis? At any rate, the advice to consult a physician when suspicious symptoms arise should be followed always. The public require more information from the doctor as to exactly what these suspicious symptoms are.

PREDISPOSING CAUSES OF RHEUMATISM

Tradition has it that rheumatism is a cosmotelluric disorder. In other words cosmic factors such as rainfall, humidity, variations in temperature and barometric pressure, diminished ionization of the air and so on combined with telluric conditions, notably soil dampness, play an undoubted if ill understood rôle in producing acute and chronic rheumatic disorders.

Miller discussing cosmic or climatic conditions dismisses them with the trite observation that damp and cold indisputably account largely for the prevalence of rheumatism in the British Isles. The influence of cosmic forces on the organism, we think, merits something more than an almost flippant allusion thereto. Are we to rest satisfied with the mere statement that damp and cold predispose to rheumatism—as if forsooth the pronouncement were selfexplanatory and final! Are cold and damp the only cosmic factors concerned? May not lack or excess of sunshine play a part not to speak of barometric variation or changes in ionization and other conditions?

The laborious researches of Haldane, Barcroft and other physiologists must assuredly have fallen on stony ground, otherwise some reference would have been forthcoming as to the truly profound influence exerted by variations in temperature, humidity, and barometric pressure on the vital processes of tissue oxygenation. For, all these factors raise or lower the dissociation curve of oxyhemoglobin and this minute by minute in strict accord with the fluctuating need of the tissues for oxygen. The absence of any

reference to these well ascertained physiological findings is the more inexplicable in that it possibly explains why the English climate is so provocative of rheumatism. This we suggest because its salient characteristic is its variableness, its erratic changes in temperature, humidity, pressure, all throwing strain upon the physiological powers of adaptation, i. e., of tissue oxygenation. This was well described by Llewellyn in his presidential address on The Rheumatic Diatheses. As he rightly observes, if the problem of rheumatism is ever to be solved we must envisage the rheumatic subject, young or old "as an organic unity under the play of cosmic forces, as a living being whose life is but a fragment of the total life of the universe." Had the farreaching effects of cosmic variations on tissue oxidation been duly considered, as they undoubtedly ought, when discussing the predisposing influence of climatic conditions, we venture to think that certain rash conclusions would have been modified. Thus Miller observes "It would appear that the proximity to water, the subsoil, and the altitude of the site have all some predisposing power towards rheumatic infection, but it is very necessary that their importance should not be overemphasized. If there is anything in the connection between damp homes and rheumatic infection, it is the dampness of the home itself which is primarily of importance. Its site is only of secondary importance as tending towards a damp home. That it is perfectly possible to live in a lowlying district close to water without the slightest fear of rheumatic infection is proved beyond criticism by the experience at Eton and Beaumont Colleges. Both these lie close to the Thames and between them account for some 1,350 boys, and yet I am told by Dr. Atlee that he has seen only one case of rheumatic fever at Eton in seventeen years, and Dr. O'Ferrall no single case in eight years."

Rheumatic subjects may well take heart of grace. Even though they live, so to speak, in a swamp, they shall be immune not only from rheumatism but even from the fear thereof, provided their house be dry.

If a dry house be the one thing necessary to salvation, then apparently the mystery of how to prevent rheumatism is solved. But what becomes of Dr. Miller's previously expressed faith in the potency of climatic conditions? Does a dry house immunize the dweller therein not only from rheumatism, but from the effects of climate also? Again why attach primary importance to a dry house and but secondary importance to proximity to water, subsoil and altitude? For if we eliminate defective roofing, and pervious walls to what can the dampness of a house be attributable, if not to site or soil dampness? The wise man has from time immemorial built his house upon a rock and despite Miller's dictum will, we venture to think, continue to do so. For, in truth "the floods came and beat" upon no few of the houses in which Miller and his colleagues found the majority of their rheumatic cases. In Marylebone subterranean rivers and in Paddington canals abound, while Bath and Bristol are traversed by canals and rivers and in Birmingham "the great majority of the cases occurred along the southern banks of the two streams which flowed through the town" and in which the streets "are periodically flooded." Again the subsoil in these various regions were dominantly clay, river bed, alluvial or gravel and in respect of the last named we are told that in Bath "the gravel in the majority of these cases is in an area adjacent to the river bed and used to be flooded."

As to alfitude we are told that the London cases almost all dwell in lowlying areas, and much the same is true of Bristol and Bath, and yet in the next paragraph we are cautioned not to overemphasize the importance of proximity to water, subsoil and altitude. We venture to think that Miller's evidence overwhelmingly points to the above factors being of primary importance and dryness of the house of secondary valency.

The *British Medical Journal* in an editorial expresses a pious hope that the public health authorities will see to it that "the new houses of the people will be in this respect (dampness) an improvement on the old." Nevertheless, we doubt if the Ministry will share Miller's relative indifference as to the site, subsoil or altitude of the houses they may elect to build. Dr. Miller holds that "industrialization" is a "powerful predisposing factor" and we recall the following data drawn from the Health Ministry's invaluable report on the "incidence of rheumatic diseases." It reveals that of English counties the incidence and death rate from acute rheumatism and cardiac rheumatism is highest in Lancashire—an industrial region. Nevertheless, the incidence and mortality from these same disorders is higher still in Montgomeryshire, an agricultural county in Wales. Again "social status," he says, is a powerful predisposing factor. Truly a novel doctrine. Since when, may we ask, have rheumatic streptococci been influenced in their choice of victims by their status, high or low, in the social hierarchy. Somewhat of a strain, this, upon our powers of orientation but Miller is a pitiless iconoclast with no bowels of compassion. Nothing is sacred not even the germ plasm, usually held inviolate. For lo and behold we are told in respect of rheumatism that "the importance of heredity is more apparent than real; its frequency is largely a matter of home environment." Small wonder that in the next sentence he hastens to tell us with truly "damnable iteration" that "it is the state of the house rather than its site which is important." Truly the lot of the builder is hard but what of the social welfare worker, when he realizes that "home environment" determines the frequency of an hereditary predisposition to rheumatism.

The purpose of the research was to inquire into "rheumatic heart disease in children," its prevention being the prime objective. But in Miller's Report on the Environmental and Other Predisposing Causes of Rheumatic Infection, we look in vain for any light on the factors that especially favor or produce heart disease in childhood. Heredity goes by the board despite the fact that in both the Bath and Bristol cases it figured strikingly. Again the influence of malnutrition we are told is undoubted though "its action, taken alone, is probably not a potent one." Again in discussing nutrition and diet surely some mention should have been made of the tendency of these children to acidosis, cyclical vomiting, mucous colitis, etc. As to the old view that "there was some metabolic predisposition towards rheumatism in certain individuals or families," Miller observes "applied to the definitely infective rheumatism of children I

see no room for the theory." We have yet to learn that the rheumatism of childhood is definitely infective. Pontifical statements of this sort, even when reiterated *ad nauseum* are merely statements and not demonstrations. Again we are told that "the key to the rheumatic problem would be in our hands if we knew why the disease in its definite forms is one of hospital as opposed to private practice." This *ex cathedra* pronouncement is far too dogmatic. If accepted it will retard rather than advance our knowledge and we disagree wholly that its elucidation will prove to be the open sesame we all hope for. All that experience justifies us in claiming is that rheumatism, cardiac or other, is more common in the children of the poor than of those more happily situated. Were acute rheumatism and cardiac rheumatism, as they should have long since been, among the list of notifiable diseases, this opinion as to class distinction would never have been voiced, much less have been exalted as an axiom for our guidance in further research. To sum up, the investigations, far from shedding light, do but accentuate our ignorance of the environmental and predisposing causes of rheumatism.

Dr. Miller's report will be fortunate if it escapes the obvious criticism "What is new is not true and what is true is not new."

Obituary.

SIR FREDERICK MOTT, F.R.C.P. LOND., LL.D. EDIN.

London

Death has been busy recently in the ranks of the British medical profession. Within the space of a few weeks several well known leaders of the profession have passed away. Stephen Paget, John Williams, Caultie and Leishmann and now Frederick Mott, who died on June 8th, in Birmingham General Hospital at the age of seventy-two. He had a seizure while traveling in the train from London to Birmingham a few days ago.

Mott was undoubtedly one of the makers of modern medicine and gave to the study of mental diseases a new aspect. He insisted that many mental disorders had a physical basis, a view which a large number of alienists and neurologists now hold. Mott saw insanity, or many forms of mental aberration, not as a disease of the soul or mind, but as a disease of the body. He believed, in short, that given a sound body, as a rule, a sound mind would be housed therein. Of course, this view is not new, but Mott not only voiced this opinion; he set to work to prove it.

In this endeavor he was remarkably successful. He showed that general paralysis was syphilis of the brain. This was a most important discovery. "G. P. I.," before the time of Mott, represented a classical disorder of the mind characterized by symptoms of delusions of grandeur and so on, and had been studied intensively for generations. Mott's monumental investigations removed this malady from the mental to the physical sphere, and although this view has been attacked from various quarters, it has withstood the acid test of experience and is now generally accepted. Further testimony of the physical basis of general paralysis of the insane has been afforded by its successful treatment in some instances by the artificial induction of malarial fever.

Mott next took up the study of dementia precox. However, the war interrupting this study, he turned his attention to solving the problem of "shell shock" and threw much light upon this subject.

Mott was a pathologist of the very first rank and was honored as such in every civilized country. Most of his best work was done as pathologist to the London County Asylums, where he had access to a wealth of material. In this post he was associated with another great neurologist, the late Mr. Maudsley, and Mott was active in instituting the Maudsley Hospital in South London as a memorial to that great man.

Mott was born in Brighton in 1853 and educated at University College. He was associated with the late Sir Victor Horsley in certain brain researches. He was consulting physician to Charing Cross Hospital and when he retired from his London post he became associated with research work in Birmingham. The *London Times* of June 9th, in an appreciative memoir of Mott, says, "No kinder or more gentle man ever lived."

DR. LILIAS HAMILTON

Kabul

A truly remarkable woman died a short time ago in Nice in the person of Dr. Lilias Hamilton. She was an extremely good physician and of great personality who passed an adventurous life such as falls to the lot of few men and still fewer women.

Dr. Hamilton was a student of the London School of Medicine for Women, taking her degrees in medicine in London and Brussels in 1890. She first built up a large practice in Calcutta and when the offer of the post of Court Physician to the Amir of Afghanistan, Abdul Rhaman, came, the Indian Government told her plainly that if she went she did so entirely at her own risk. Although her health was by no means good at the time, she decided to take the risk. However, she quickly justified the choice that had been made, was a great success as Court Physician, and opened a hospital at Kabul, to which came all sorts and conditions belonging to the wild tribes of the frontier and the border. As may be well imagined in dealing with the Amir great tact and good judgment had to be observed.

On her return to England she worked for a time at the Liverpool Settlement among the poor, and in 1908 went as Warden to the Studley College of Agriculture and Horticulture for Women, of which she made a great success. She had visited South Africa and had realized something of the possibilities of land for girls. Up to last year she remained there as principal, although during the epidemic of typhus in Serbia early in the war, she went to do what she could for the suffering people. She died in Nice somewhat unexpectedly after a very full and varied life in which she proved once more not only the worth of the medical woman but that she can undergo hardships with as high a spirit as man.

The Harvard Medical School and the Region Round About It

History of the Harvard Medical School

F. C. SHATTUCK, M.D.

Boston, Mass.

The history of the Harvard Medical School, its foundation and growth, may serve to illustrate the history of medical education in this country, although the University of Pennsylvania, 1765, and the University of New York, 1768, are elder sisters.

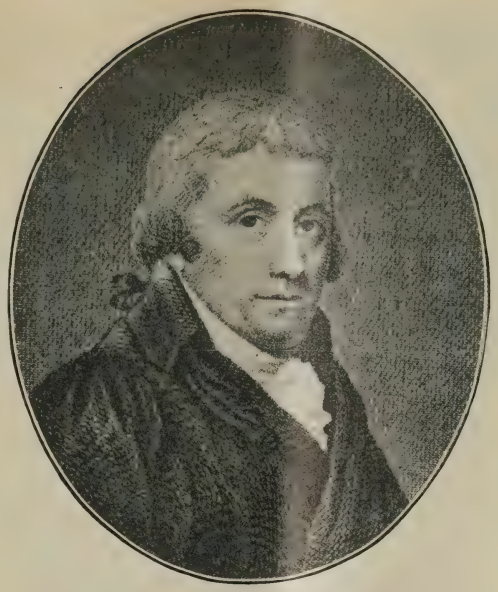
In the century and a half which elapsed between the Virginia settlement and the first medical school an official qualification for practice was held only by the few immigrants who brought it with them, and those Americans who could afford to seek it in England or Europe. The avenue to practice was through apprenticeship, which often turned out practical, resourceful men, ready to deal with anything coming along. They were not spoon fed. Some preceptors did much for their pupils, others less. I have heard one pupil quoted as saying of his preceptor, a leading Boston medico,—"All he ever did for me was first to hand over Booerhave's works in ten volumes, and then, after reading these, Van Swieten's Commentaries thereon in twelve volumes." On the other hand, a Harvard A. B. of 1765, a student of Dr. Oliver Prescott, of Groton, a country practitioner, won a place in Thacher's Medical Biography. As the country grew, so did advanced education. Travel was difficult and costly, and New England felt the need of a school of medicine all her own, naturally in connection with her chief institution of learning and near her largest city.

The Massachusetts Medical Society was incorporated in 1781 with thirty-one members, of whom twenty-three were Harvard graduates—men of preliminary training.

PERIOD I.—THE FOUNDING—1783-1811

In 1783 the Harvard Medical School was born, with three professors, Aaron Dexter, John Warren, and Benjamin Waterhouse. The two former were Harvard A. B.'s. The latter, throughout the Revolutionary War, studied three years in Great Britain under the direction of John Fothergill, his mother's uncle, and then four years in Leyden, where he took his degree, returning in 1782. Waterhouse's chief distinction is that he, in July, 1800, first in this country, vaccinated his son, five years old, for smallpox. Incidentally, it may be added that Zabdiel Boylston, of Boston, in 1721, first in America, inoculated for smallpox his son of thirteen, and two negro servants. The suggestion came from Cotton Mather, but for the backing of whom and other clergymen it probably would have gone hard with Boylston, so strong was popular feeling against such an experiment.

The lectures were given in Cambridge in quarters loaned by the College, largely to undergraduates, and it was five years before the degree of Bachelor of Medicine was first given to two men. The M. D. degree was not given until 1811. From 1788 to 1810 fifty-seven degrees of M. B. were given to men, forty-one of whom had previously received a degree in arts. This is interesting as indicating that the appeal to medicine was more limited to trained men than it afterwards became, when in recent times leading schools, as a means of raising standards at whatever risk of limiting numbers and revenue, one after another made the B. A. degree or its equivalent a requisite for admission. It was a day of small things —but pregnant.

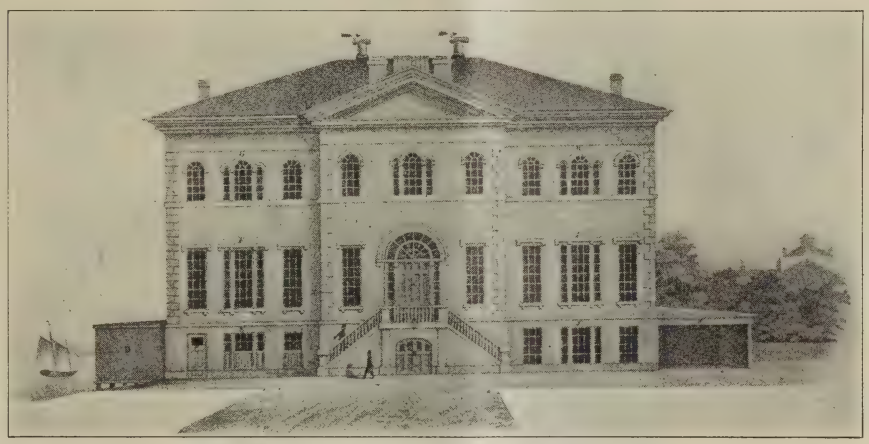


BENJAMIN WATERHOUSE

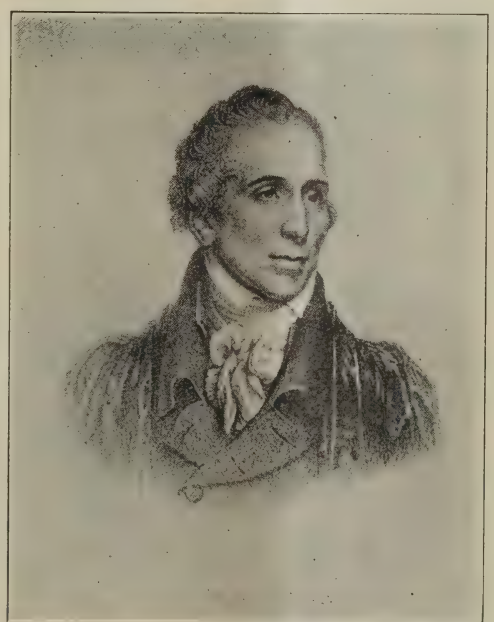
PERIOD II.—1811-1869

Our second period opens with the removal of the Medical School from Cambridge to Boston in 1811. It was a period of slow but steady growth, as real though not as spectacular as that of the country in extent, wealth and population. In the years 1788 to 1813 only twice was the maximum of five annual graduates reached. From 1813 to '25 the teens prevailed. From '25 to '37, the twenties. In '47 and '48 there was a gain into the forties, not reached again until 1860. Then came the fifties and sixties, and in '66 an even hundred graduated, the maximum of this period, and not equalled or surpassed until 1894.

The gain in methods, clinical teaching and size of the teaching body was greater than that of the student body. For the Harvard school did not long have a monopoly in New England. Nathan Smith, a giant of American medicine, Harvard M. B. 1790, as sole professor founded the Dartmouth school in 1798; that of Yale in 1812, of Bowdoin in 1821, and lectured at the University of Vermont 1822 to '25. Verily, there was no racial or other suicide about him. He left four sons and a daughter, all the former men of medicine. Until well into the latter half of the last century the Harvard School had a fair number of Canadians, especially from Nova Scotia and New Brunswick. These fell off as home conditions improved and Harvard standards were raised. Other competitors arose. It is a truism that there is no such way to learn as to try to teach others. The Berkshire School at Pittsfield was incorporated in 1823 under the jurisdiction of Williams College. Cheap living and good teaching soon attracted students to a number about equal to those of Harvard. Among the teachers Alonzo Clark, O. W. Holmes, Willard Parker, Elisha Bartlett and Gilman Kimball may be mentioned. After 1845 it gradually declined from lack of clinical advantages and other causes, and its last catalogue was issued in 1867.

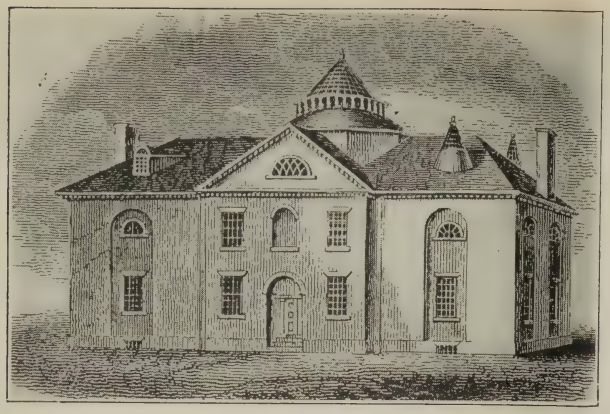


Massachusetts Medical College, Erected 1846



JOHN WARREN

Private schools also arose in Boston, chief of them the Tremont, '38, and the Boylston, '47. The underlying cause for their existence was doubtless the short lecture term of the Harvard School and a gradual drifting away from the preceptor system. The teachers were Harvard graduates or even Harvard teachers. These schools, extramural in part, filled time between the lecture terms of the Harvard Medical. They admirably served their purpose, and were finally given



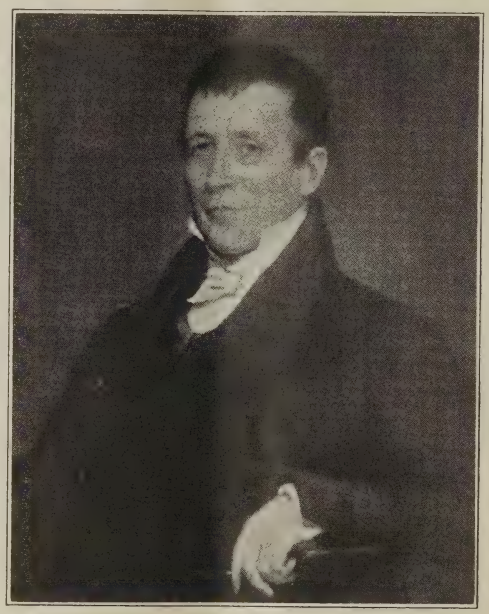
Massachusetts Medical College, Erected 1815

up or partly merged with the more powerfully backed Harvard. For the interesting details of the story space here lacks.

Among the professors of this period were John C. Warren, James Jackson, O. W. Holmes, the brothers Jeffries and Morrill Wyman, Jacob and Henry J. Bigelow, father and son; J. B. S. Jackson, Henry I. Bowditch, George C. Shattuck, Edward H. Clarke, David W. Cheever and Calvin Ellis. Some of these held over into the next period.

An outstanding event of this period was the first major operation under ether, at the Massachusetts General Hospital by John C. Warren in 1846.

Until 1816 the School had no habitation of its own. Then was built and opened, with State aid, a centrally located home in Mason Street, which gave place in '47 to the North Grove Street building, much larger and adjoining the Massachusetts Hospital. The School seems to move about once in a generation. It is to be hoped that the present generation will be a long one.



J. JACKSON

PERIOD III.—1869-1909.

This period covers the presidency of Mr. Eliot, marked by radical changes and great development educationally and materially. Up to this time the Harvard Medical School was practically a proprietary school. The University conferred degrees but had no control over the finances, and little voice in appointments. The endowment was meagre. Faculty meetings were presided over by the Dean, at whose house they were usually held. The Medical Faculty paid the bills and divided up any surplus. Mr. Eliot at once took the chair at Faculty meetings. In '70 Dr. Holmes writes to J. Lothrop Motley, then Minister at the Court of St. James,—"Our new President, Eliot, has turned the whole University over like a flapjack. There never was such a bouleversement as that in our Medical Faculty."

The property of the school and its receipts were put under the charge of the treasurer of the University, the professors under salary, and in 1871 a three-year graded course with written examinations and the requirement to pass in every branch was instituted.

Before this the examinations were oral and the candidate was required to pass only a majority of the branches for a degree. It needed all Mr. Eliot's firmness and calm persistency to bring about these first changes against the active opposition of some influential professors. No one in 1870 could have foreseen the impending revolution in medicine caused by Pasteur and his followers. Knowledge of the cause of disease fathered knowledge of its cure and prevention, with the results we see today. This, of course, played directly into the hands of Mr. Eliot, but does not minimize in the least his desert. No man of his time has done so much for education, medical included, as he. None the less were his foresight and tenacity favored by circumstance.

Toward 1880 the North Grove Street building became woefully inadequate, and generous friends made it possible to put up a new building on Boylston street, midway between the Massachusetts and City Hospitals, likely, it was thought, to meet all needs for many years. This building was opened in 1883, the centennial of the founding of the school. Within a few years a welcome addition was given by Dr. H. F. Sears. But laboratory demand clamored for expansion, and toward the end of the century H. P. Bowditch and J. C. Warren, eagle-eyed and lion-hearted, laid their plans. Elsewhere[1] I have told the dramatic story of the wonderful realization of their dreams, a story by itself, and can here deal only with results. Twenty-three acres of suitable land were secured within the city limits, enough for the School and a number of affiliated hospitals and institutions. In 1906 the new school buildings were opened with enough endowment pro-

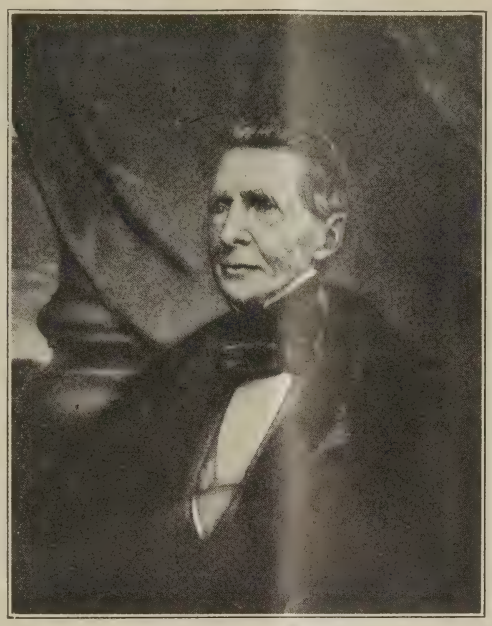
[1] *Boston Medical and Surgical Journal*, Vol. 193, No. 23, pp. 1058-1061, Dec. 3, 1925.

vided for their frugal and immediate maintenance.

During this period a fourth year, at first optional, later required, was added to the course, and the teaching body was more and more recruited from outside Boston, as gentlemen's agreements with far seeing trustees of leading hospitals were entered into, thus making it possible to give a clinician his laboratory in the form of hospital wards. One after another, the Peter Bent Brigham, the Children's and Infants', Samaritan, Huntington, and Lying In Hospitals have clustered about the School; also the Psychopathic Hospital, Carnegie Nutrition Laboratory, Dental School, Animal Hospital, and the School of Pharmacy.



JOHN C. WARREN

The admission of women has been repeatedly urged upon the School, and wisely, as it would seem, as repeatedly denied. Today four times the number of men apply for whom there is place, and there is now no lack of first rate teaching for medically inclined women. Medical education is the costliest there is, and it is uneconomic to train too large a number of those who do not make the profession their life work. Harvard is almost the last refuge of mere man.

PERIOD IV.—1909-1926

After forty brilliant years President Eliot was succeeded by President Lowell. Under Mr. Lowell's administration there has been great and steady progress all along the line. Its outstanding features have been

I. The introduction of what may be termed optional full time into the clinical branches. The selection of the professor is based only on his quality. He is at liberty to do private work if he pleases, trusted to put his school work first. There are those who believe that a clinical teacher may not be damaged by seeing some patients outside of a hospital.

II. The birth of the tutorial system—an extremely healthy child.

III. A painstaking study of examination methods, which have undergone several changes. Under the present plan the student must pass in every branch as before, but he must also pass a stiff final general examination supervised by a committee and carefully designed to test his knowledge of medicine as a whole, as well as his power to use such knowledge. This examination lasts two or three days and may be partly oral. This plan has been in operation since 1920 with very satisfactory results.

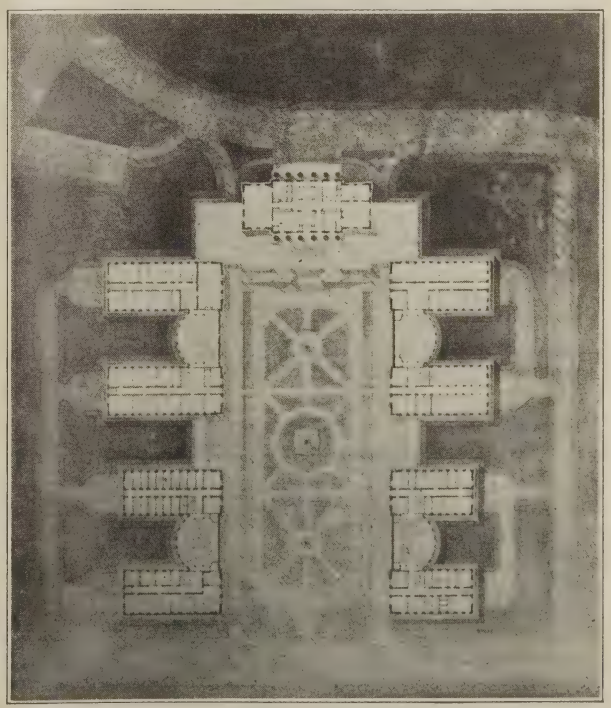
IV. The School of Public Health. One after another, supplementary to the Chair of Hygiene and Preventive Medicine, the School for Health Officers jointly with the Institute of Technology, and the Departments of Tropical Medicine and Industrial Hygiene had come into being. In 1922 all these were welded into the School of Public Health through the backing of the General Education Board. In law the School of Public Health is a separate organization. In fact, it is an integral working branch of the Harvard Medical School.

V. The Dean, Dean also of the Dental School, and School of Public Health, consecrates his whole time to his diaconal duties.

VI. A dormitory for the medical students is nearing construction. It was first suggested in print by Warren in 1912. It is planned to house and feed at the start two hundred and fifty men, with common rooms, dining room, gymnasium and squash courts. The medical student will thus soon enjoy the advantages of healthful living and association hitherto confined to students in other branches of the University at Cambridge three miles away. Alumni of the Medical School have given more than $100,000 toward the dormitory. Mr. Harold S. Vanderbilt gave $125,000 for the gymnasium with a promise of the salary of the director for five years, and later gave $575,000 for the buildings.

The table on following page may emphasize some of the changes of forty years.

This endowment seems—and is—large. Most of it is, however, restricted. If it were large enough the School would be in danger of dry rot. To live



New Buildings for the Harvard University Medical School, Boston

aggressively some hunger pangs are needed. It is the firm intention of those in power to keep demand ahead of supply. The pay of the teachers, especially

	Number of students.	*Number of teachers.*	*Endowment land, buildings and equipment not included.*	
1883	243	47		$ 200,000
1926	505	331	Medical School	11,500,000
			School for Public Health	1,750,000

those of lower grades, could be increased without risk of the somnolence of hypernutrition. This alone would absorb annually a large sum. Then there are the ever expanding avenues to and outlets from research, and the extension of the tutorial system.

The next table is interesting as showing the relative growth of the clinical and laboratory staff, and indicating the substitution of section work for didactic or clinical lectures in the clinical branches:

	Number of Teachers.	
	Clinical	*Laboratory*
1900	58	48
1913 Increase over 1900	246 per cent.	142 per cent.
1926 " " "	391 per cent.	227 per cent.

I cannot close better than by quoting in essence a brilliant professor coming from high place outside to Harvard with which he had no previous association: "The Harvard Medical School is fortunate in that, closely affiliated as it is with three great general hospitals, the clinical teaching is so varied as to tend to a broader outlook than in schools with a single hospital dominated by a single plan. The training is not stereotyped; the student does not come out as the product of an individual professor and his assistants, but learns that there are different points of view and more than one method of attaining the same end. In this respect it resembles Vienna and the larger German university schools."

It is hard to believe that the future has in store any such revolution in medicine as came about in the last half century through our knowledge of lower forms of life and their relation to vital processes of health and disease. Great changes, however, are bound to come. The general public is daily realizing more fully what medicine in the broad sense means, and I do not believe that the golden stream for irrigation will shrink. While I lack imagination to visualize the progress of the next fifty years I abound in faith, faith that there will be great progress, and that the Harvard Medical School will play a worthy part therein.

News Items.

Ensworth-Central Medical College Meeting.—The Ensworth-Central Medical College Alumni will hold their second annual meeting and banquet on the evening of October 13, at the Hotel President, Kansas City, Mo. This will be during the Kansas City Fall Clinics week. A program of unusual interest has been arranged.

New Jersey Medical Society Headquarters.—A resolution authorizing the establishment of permanent headquarters for the Medical Society of New Jersey was adopted on June 19 at the close of the one hundred and sixtieth annual meeting of the association at Atlantic City. It was the understanding that Newark, Trenton or Atlantic City will be chosen as the place for the headquarters, which will be devoted largely to public health education.

Red Cross Roll Call.—The American Red Cross has announced that its annual roll call to enlist members for 1927 will be held as usual from Armistice Day to Thanksgiving, November 11-25.

Conference of Health Workers Postponed.—The annual conference of health officers and public health nurses, originally scheduled for August 31, and September 1-2 at Saratoga Springs, has been postponed until October 11-14. It will be held in conjunction with the annual meeting of the American Public Health Association at Buffalo.

New German Health Resort Hotel.—Eilsen in North Germany, about three hours from Bremen, has just opened a new Kurhotel in addition to the well known Fuerstenhof with its American manager. This opening will be celebrated by a special reduction in rates so that those of moderate means may enjoy a sojourn in the beautiful Weser Mountains.

International Dentistry Congress.—The seventh international Congress of Dentistry will be held at Philadelphia, August 20-28. The American Dental Association has chartered a vessel to bring delegates from Europe, and in addition German dentists will come in a special ship. The Army, Navy and Public Health Service, and the governments of Germany and Japan will have exhibits. One whole day will be devoted to clinics which will cover all the aspects of dentistry.

International Stomatological Congress Members.—The following were appointed members of the American Committee of the fifth international Stomatological Congress of the *Association stomatologique Internationale* to be held in Paris in 1927: Dr. Alfred J. Asgis, Chairman; Dr. G. Reese Satterlee, treasurer; E. B. Hardisty, recorder; Dr. Oliver T. Osborne, New Haven; Dr. George W. Mackenzie, Philadelphia; Dr. Edward C. Briggs, Boston; Dr. William G. Shomeley, Philadelphia; Dr. Anthony Bassler, New York City; Dr. Louis Ottofy, Chicago; Dr. Weston D. Bayley, Philadelphia; Dr. W. E. Hocking, Devil's Lake, N. D.; Dr. F. M. Dimas Aruti, San Juan, P. R.; Dr. William G. Downs, Jr., Evansville, Ind.; and Dr J. M. Murphy, Temple, Texas.

French Government Decorates Twelve.—Twelve workers at the French Hospital, 450 West Thirty-Fourth Street, New York City, were decorated by the French Government for service to mankind on June 17. Those receiving the medals were Sister Mary of St. Elizabeth, superintendent of the hospital; Sister Mary of Eudoxie; Helen M. Moire, director of nurses; Lelia Townsend, president of the Nurses' Alumnae Association; Mrs. M. G. Bobser, superintendent of the Social Service Department; Dr. Lucien Jouvaud, president of the hospital; Dr. J. P. Hoguet, attending surgeon; Dr. P. R. Turnure, vice president of the Medical Board; Dr. M. A. Ramirez, secretary of the Medical Board; Dr. C. H. Chetwood, attending surgeon, department of urology; Dr. M. I. Blank, associate attending surgeon.

U. S. Civil Service Examinations.—The following civil service examinations have been announced by the U. S. Civil Service Commission:

Junior medical officer (interne). Applications for junior medical officer will be rated as received until August 31. The examination is to fill vacancies in Veterans' Bureau hospitals and diagnostic centers, and in positions requiring similar qualifications.

Physiotherapy aide; physiotherapy assistant. Applications for these positions must be on file at Washington, D. C., not later than August 7, October 9, or November 27. The dates for assembling of competitors will be stated on admission cards sent applicants after the close of receipt of applications. Applications received after a closing date will be considered for the next date. The examinations are to fill vacancies in the field service of the Public Health Service and the Veterans' Bureau, and a vacancy at St. Elizabeth's Hospital, Washington, D. C.

Graduate nurse, graduate nurse (visiting duty). Applications will be rated as received until December 30. The examinations are to fill vacancies in the Departmental Service, Washington, D. C., in the U. S. Veterans' Bureau, and in the Indian and Public Health Service.

Trained nurse, trained nurse (psychiatric). Applications must be on file at Washington, D. C., not later than August 7. The date for assembling of competitors will be announced on admission cards sent applicants after the close of receipt of applications. The examinations are to fill vacancies in the Panama Canal Service.

Book Reviews

NEPHRITIS

Nephritis. By Herman Elwyn, M.D., Assistant Visiting Physician, Gouverneur Hospital, New York, N. Y. New York: The Macmillan Company, 1926. Pp. 347.

After discussing the physiology of the kidney and such conditions as renal insufficiency, hypertension, and uremia, the classification of nephritis is taken up. While the ideal classification of nephritis, in which each type of the disease finds its place as a distinct and separate entity with a definite etiology, pathology, and clinical picture, is impossible at the present time, an attempt at such a classification can be made only where we can find a correlation between the pathology, the symptoms, and the change in function in a particular form of nephritis, and especially where we can find definite etiological factors.

The importance of the glomeruli in nephritis is emphasized, and the author recognizes the following forms: embolic glomerulonephritis, nonembolic focal glomerulonephritis, acute diffuse glomerulonephritis, subacute and subchronic forms of diffuse glomerulonephritis, chronic diffuse glomerulonephritis and the kidney of pregnancy. The nephroses are divided into lipoid nephrosis, the nephrosis of amyloid disease and the nephrosis of mercury poisoning.

After dilating upon the pathology, etiology, and pathogenesis of general arteriosclerosis, the subject of renal arteriosclerosis in particular is discussed. Arteriosclerosis of the kidney involving the small arteries and arterioles, the renal arteriolosclerosis of Herxheimer, a term which is becoming quite popular, is classified as follows: 1, renal arteriosclerosis involving the renal artery and its larger branches; 2, renal arteriolosclerosis without renal insufficiency, involving the small arteries and arterioles, but without the loss of a sufficient number of glomeruli to affect kidney function; 3, renal arteriolosclerosis with renal insufficiency, involving the small arteries and arterioles, with complete occlusion of many of the afferent arteries, and with the loss of a sufficient number of glomeruli to affect kidney function.

The following novel hypothesis regarding the kidney of pregnancy is presented: Throughout pregnancy there is a gradually increased irritability of the entire neuromuscular mechanism which has to do with the function of uterine contraction, producing eventually the rhythmic contractions of the uterus and the contraction of labor. This increased irritability is probably dependent upon a state of increased irritability of the presiding centers in the brain. Afferent external stimuli, psychic or physical, may also cause arterial spastic contraction. This hypothesis has the advantage of eliminating the necessity for an unknown toxin. It attempts to explain on a physiological basis the occurrence of arterial spasm, which may produce renal phenomena, the edema, the hypertension, and the convulsions.

On the whole, this book is rather an exhaustive treatise of what is known of nephritis today. The clinical picture of each type of nephritis is correlated with the corresponding pathologic changes. Each chapter has its own very extensive bibliographic references, which include German, French, English, as well as American citations. Diagnosis and treatment are well emphasized. The book is a worthy addition to the literature on nephritis.

DERMATOLOGY IN FINLAND

Förhandlingar vid Nordisk Dermatologisk Förenings Sjätte möte, Helsingfors 26-28 Aug., 1924. Utgifna af J. J. Karvonen och B. Grönroos, Helsingfors.

The Northern Dermatological Association held its sixth congress in Helsingfors, Finland, on August 26 to 28, 1924, and among the varied contributions on their program of skin and venereal diseases are noted the following:

Congenital Syphilis in children at the Infant Home of the Child Welfare Committee of Copenhagen, Harald Boas reports results with forty-eight children treated in this home, patterned after the Welander Home for Syphilitic Children in Stockholm, established in 1900, to give adequate treatment to congenital syphilitics during the first three to four years of their life, thereby endeavoring to ward off physical and mental defects among a social class that would otherwise be neglected. Other Welander homes have been established in Gothenburg and Malmö, Kristiania and Bergen, Berlin and Prague. The Copenhagen Welander Home, founded in 1909, cares for children from the very worst classes of society and is conducted rather differently, admitting not only babies but fourteen to fifteen year old children that are congenital luetics, these latter being sent to public schools while undergoing treatment and to prevent the inmates from being stigmatized the name "Home for Infirm Children" is used. As to results of treatment of the forty-eight children—with mercury, altsalvarsan and neosalvarsan—of which a detailed report is given, the final accounting up to date is that twenty-six have been discharged (twenty-two still remaining in the home) and of these only two are failures, one being sent to an institution for mental *debiles,* the other to a reformatory as incorrigible. The remainder have entered life as artisans, laborers, dressmakers and servants and with encouraging records.

Potassium permanganate and its therapeutic efficacy in skin diseases was the subject of a dissertation by C. Rasch, of Copenhagen, who finds it useful in local prurigo and psoriasis, painting with a two per cent. solution or as ointment according to Unna (Kali permang 1, Tinc oxide 10, water 10); in moist eczema and salvarsan dermatitis the "red baths"—ten grams permanganate to the bath—have given excellent results and also in impetigo herpetiformis.

Gonorrhea in male children was the topic presented by Ake Ingman (Helsingfors) who reports ten cases in children from two to twelve years of age. Arthritis gonorrhoica artic. cricoarythenoideæ, a rare condition, was the contribution of Paavo Pirilä (Helsingfors), described as occurring in a man with recent Neisser infection, all other etiological factors being carefully excluded. Johan Almquist of Stockholm discoursed on the curability of gonorrhea. (Published in *Acta Dermato-Venerealogica,* Vol. VI, Fasc. 3, Stockholm, 1925.)

Salvarsan injections and the grave disturbances at

times following these—crises nitritoïdes—was the subject presented by Axel Cedercrentz (Helsingfors), who observed six cases in close sequence, and while the origin of such manifestations as cyanosis, chills, nausea, diarrhea and fever are still obscure, he believes that it may be arsenical poisoning, caused by oxidation of the salvarsan contents in contact with the metal of the syringe.

Acrodermatitis continua (Hallopeau) a condition so rare that up to 1918 only fifteen cases had been reported was discussed by James Stoandberg (Stockholm), his experience with three cases being described in detail.

Medicoliterary Notes.

Dr. Edward S. Godfrey, Jr., director of the Division of Communicable Diseases of the New York State Department of Health, has an interesting and suggestive article in the *American Journal of Public Health* for June on the Administrative Control of Measles.

* * *

The U. S. Department of Commerce, in its published report of automobile fatalities for the four weeks ending June 19, 1926 from seventy-eight large cities in the country, states that the total number was 549 as contrasted with 493 for the corresponding four weeks of 1925. The daily averages for the two four-week periods were 19.6 and 17.6.

* * *

Among articles of importance on the subject of child welfare in the June issue of the *American Journal of Public Health* are Immediate Opportunities in Child Health Conservation, by Dr. Donald B. Armstrong; Examination of the Child Before Entering School; and Relation Between Health Supervision on Schools and Industries, by Dr. Ellen S. Stadtmuller, and Dr. C. O. Sappington, respectively.

* * *

The Argentine battleship, Moreno, is enroute to Buenos Aires with two thousand minnows as part of its cargo. These will be used in an effort to stamp out malaria in the Argentine Republic, which they do by feeding on the larvae of the mosquitoes carrying the malaria germ.

* * *

A recent survey by the U. S. Children's Bureau shows that, although child indenture is looked upon as a relic of the age when handicrafts flourished, it is still permitted in twelve states of the Union. For instance in Wisconsin 827 children were indentured on written contracts by the State Public School at Sparta under a law enacted in 1885. Many of the children received virtually no pay, were looked upon as servants, often deprived of school, allowed no recreation, and sometimes cruelly treated.

* * *

Thirty-six organizations, most of them national in scope, represented by sixty research workers, are cooperating with the U. S. Bureau of Standards in helping to solve industrial problems. The purpose of these cooperating activities is to make available well equipped laboratories for the mutual benefit of government, workers and public.

* * *

An interesting bibliography, published in the June number of the *Monthly Labor Review*, has been compiled by Edna L. Stone, librarian of the library of the U. S. Department of Labor, on the subject of old age pensions in the United States.

* * *

The eternal flapper has existed in the Chinese Empire since the Christian era, according to a note in the *Science News Letter*. Two powder boxes dating back to the Han Dynasty, 200 B.C.—220 A.D., have been found in a grave in Korea. There was powder in them and it was still white after the passage of so many centuries.

* * *

The *World's Health* for June contains a number of interesting articles on welfare and medical aid for sailors. They are an introductory article entitled The Ship Sails On; The International Labor Office and the Protection of the Health of Seamen, by M. R. K. Burge, director of the London branch of the International Labor Office; Amongst Our Sailors, by Charles le Goffic; Venereal Disease and the Merchant Seaman, by Dr. L. W. Harrison, of the Ministry of Health, London; Activities of the United States Public Health Service on Behalf of the Merchant Seamen, by Surgeon General Hugh S. Cumming; The Seaman's Health, by Dr. F. Humbert, chief of the Health Division of the League of Red Cross Societies; The Plight of the Deep Sea Fisherman, by Claude Farrère; The Need of Welfare Work for Merchant Seamen, by Fleet Surgeon W. E. Home of the British Navy; and Hygiene in the French Merchant Service, by Dr. Henri F. Schaeffer, port sanitary officer of Havre. A reference list on the health of merchant seamen gives important reading matter in English, French and Dutch.

* * *

Forestry experts are urging the rapid using up of chestnut trees in the southern Appalachian forests before the chestnut blight, which is fast attacking all the trees, makes the wood rotten and so worthless. The organism which is killing all American chestnut trees is a fungus which was brought into the country on contaminated nursery stock from Asia a few years ago. In its native home, the fungus was not so deadly, for many of the trees had become somewhat immune to its ravages. Experiments are now being made in the hope of discovering some foreign chestnut which will resist the fungus.

* * *

The Malaria Commission of the Health Organization of the League of Nations has just issued for distribution its Reports on the Tour of Investigation in Palestine in 1925. The report discusses the past and present prevalence of malaria in Palestine as a whole, and the measures that have been taken to deal with it; appendices give the ordinances, regulations and measures for malaria control, and photographs and plans for various drainage works and other structures for this purpose.

* * *

Ninety-five leaden pellets, weighing twenty-four grams, were found in the appendix of a woman recently operated upon by Dr. Sonnenfeld of Berlin. The patient was a forester's daughter, and had swallowed the shot while eating game killed by her father. They caused no discomfort, and the surgeon discovered them while performing an operation having nothing at all to do with the appendix.

* * *

The Trudeau Sanatorium at Saranac Lake, N. Y., has recently published its forty-first annual report.

* * *

The Proceedings of the New York Pathological Society, October-December, 1925, have just been published. The volume includes Some Unrecognized Dangers in the Use and Handling of Radioactive Substances, by Dr. Harrison S. Martland; Granuloma Venereum, by Dr. Max Goldzieher and Dr. Samuel M. Peck; A Primary Squamous Cell Epithelioma of the Trachea, by Dr. Silik H. Polayes; Pathology of Fowl Paralysis, by Dr. Alwin M. Pappenheimer, Dr. Vernon Cone, and Leslie C. Dunn; Syphilitic Stricture of the Left Main Bronchus, by Dr. Chester R. Brown; Complete Transposition of Arterial Trunks, by Dr. Morris Dreyfuss; Thrombosis of the Abdominal Aorta, by Dr. Chester R. Brown; Idiopathic Dilatation of the Esophagus, by Dr. Leila Charlton Knox; and Relation of Iodine to the Human Thyroid Gland in Certain of Its Pathological States, by Dr. Richard B. Cattell.

* * *

A folk high school patterned after those in the rural districts of Denmark has been established in the hill country near Brasstown, North Carolina. It is to be called the John C. Campbell Folk School in memory of the late John C. Campbell, who began the work necessary to the later establishment of the school under the auspices of the Russell Sage Foundation. The primary of such a school is, not to fix facts, but "to enliven and enlighten." It is independent of, though sympathetic with, the church, completely outside the state system, though subsidized to a limited degree by the state; it has no academic requirements, sets no examinations, gives no credits. The whole aim is to supply real culture in the broadest and best sense of the term.

Abstracts from Current Literature

NEUROPSYCHIATRY

Neurological Conditions.—W. Sharpe (*American Journal of Surgery,* Vol. XXXIX, No. 10) states that in the operative treatment of brain injuries and in acute conditions of spinal cord lesions, particularly those affecting the cervical segments, the two periods of severe initial shock and terminal medullary edema in which no operation should even be considered, must always be remembered; extensive neurological examinations should be postponed until the signs of severe shock have disappeared; the knowledge of the neurologic lesion to be obtained by careful physical examinations, lumbar punctures, combined cisterna magna—lumbar puncture observations, etc., are of great interest to the physician and yet the patient must be in a satisfactory general condition to avoid being made worse by these methods of examination.

Intracranial Hemorrhage.—W. Sharpe (*American Journal of Surgery,* Vol. XL, No. 2), suspecting that acute intracranial hemorrhage of the newborn occurs more frequently than supposed, experimented on five hundred consecutive newborn babies with results that confirmed his suspicions. Nine per cent. of the total number were found to have hemorrhagic cerebrospinal fluid. At the same time a lengthened coagulation time of the blood was not always found. The Rodda method was used and although the bleeding time might still be lengthened and yet the coagulation time apparently be within normal limits, the great importance formally ascribed to hemorrhagic disease of the newborn as *the* etiological factor in intracranial hemorrhage seems unwarranted. Premature babies seem more liable to intracranial hemorrhage than are the ones born at full term. Breech extraction in this series is again a frequent cause of intracranial hemorrhage, and prolonged labor with and without last resort low forceps application is also a definite etiological factor.

The clinical signs in all cases were most meager and if a routine lumbar puncture had not been performed, it is doubtful whether the condition of intracranial hemorrhage could have been even suspected in many cases. Difficulty in nursing and prolonged drowsiness were the two most common signs. When coagulation of the blood of the ruptured supracortical veins is insufficient to prevent continued venous oozing, the use of blood coagulants, such as calcium lactate, mother's blood, hemostatic sera, etc., may be of value to increase the coagulability of the blood even if the coagulation time is normal. But treatment by increasing the coagulability of the blood should be combined with drainage from the cerebrospinal system of the blood already escaped from the ruptured vessels.

Treatment of Head Injuries.—J. C. Weaver (*Surgery, Gynecology and Obstetrics,* September, 1925) advocates rigorous adherence to the classification and type of treatment as outlined by Dowman, which classification he forthwith presents. Regarding the use of magnesium sulphate he adds that by way of precaution, the possibility of magnesium sulphate poisoning must be kept in mind, and care must be taken in acute traumatic cases not to confuse the symptoms of intracranial pressure with those of increased tension plus profound shock.

If, as often happens, the patient has lost large quantities of blood or has sustained complicating injuries that have brought on profound shock, then dehydration is contraindicated, as the depletion of an already impoverished and failing circulation will bring about a fatal termination.

In shock, the respiration as a result of air hunger will be above the normal rate, the temperature below normal, and the pulse rapidly rising. While in increased intracranial tension the respiration will be below normal and the temperature rapidly ascending with the pulse.

Fractional Ligation of Common Carotid Artery.—H. H. Kerr (*Surgery, Gynecology and Obstetrics,* Vol. XLI, No. 5) puts forth an operation of fractional occlusion, illustrated by three cases which produced good results, and commenting as follows: There is a definite advantage in common carotid ligation, which not only occludes the affected vessel but also the vessel from which an anastomosis might bring recurrence. The danger of common carotid ligation lies in the possible embarrassment of the cerebral circulation of that side. This complication is escaped or avoided through the collateral circulation by way of the anterior communicating or vertebral arteries. Ligation of the common carotid does not interfere with this collateral. It is necessary, however, that the collateral cerebral circulation be given a chance to develop. This is best accomplished by my operation of fractional occlusion.

Optic Nerve Affections.—H. Hays (*American Journal of Surgery,* Vol. XL, No. 2) presents several cases demonstrative of the fact that a lesion of the optic nerve may result from an inflammation or infection of the posterior ethmoid cells or sphenoid sinus which may not be evident on the most minute examination of the nasal cavities. Even most careful x ray pictures often will not throw any light on this relationship. But an experienced ophthalmologist, who knows that pressure can be exerted on the optic nerve or that a disturbance in the circulation within the blood vessels in the nerve can take place from a diseased condition of the sinuses, after ruling out every other etiological factor, may then insist that the seat of the trouble is in the posterior ethmoid cells or in the sphenoid or both.

In all these cases, the question arises as to the type of operation that should be performed. Should one be content to remove a small portion of tissue only or should he perform a radical operation? Many rhinologists believe that an aeration of these parts is sufficient—that is, that only enough of an operation should be performed to allow of freer circulation. My feeling is that the middle turbinate bone and the posterior ethmoid cells should be removed as thoroughly as possible; that a sufficiently large opening should be made into the sphenoid sinus to allow of free exploration and drainage; that enough of the anterior ethmoid cells should be removed to allow of drainage from the frontal sinus and that both antral cavities should have a large enough opening made into them to allow of subsequent washing. No matter whether the eye symptoms occur on one side only, I firmly believe that all the sinuses on both sides of the head should be explored; for one can never tell exactly which sinus is at fault or whether all the sinuses have something to do with the symptoms.

All such operations should be performed under local anesthesia. The block method of anesthesia is best because it assures an almost bloodless field. The patient should be operated upon in the recumbent position. One should use care in curetting the upper ethmoid cells. It is not necessary to probe into the frontal sinus. One is assured of free drainage of the frontal sinus if he properly removes the anterior ethmoid cells. Lastly, the opening into the antra should be made large enough to allow one to wash them out when the patient returns to the office for treatment.

Brain Abscess of Aural Origin.—Courtenay Yorke (*British Medical Journal,* February 21, 1925) reports six cases that illustrate the fact that localizing signs are frequently absent in brain abscess, and that therefore it is often difficult to know whether the cerebrum or the cerebellum is affected. In left temporosphenoidal abscess word deafness is usually present, but if the disease be well advanced, the general hebetude will make it impossible to test for sensory aphasia. Crossed hemiparesis and homolateral oculomotor paresis are, in the author's opinion, rarely present in temporosphenoidal abscess. In cerebellar abscess nystagmus and some form of ocular paresis are the most frequent localizing signs, but even these are often absent, as are also asynergia and homolateral paresis. The most significant symptom of acute brain abscess is severe pain in the head, which is subject to the most terrible exacerbations. This is an early symptom and is invariably present. It continues until a dull apathetic state ensues, which is the precursor of coma.

The best operative procedure is to open the mastoid and endeavor to find the track of the disease. On exposing the dura the presence of a brain abscess is usually either immediately obvious by the escape of pus through a hole in the dura or suspected on account of inflammatory changes in the dura. Occasionally, however, the dura appears normal

and in such cases the dura should be incised and the brain explored. Should the patient's condition be very critical and the signs be those of temporosphenoidal abscess, it is better not to disturb the mastoid but to make a vertical incision above the ear and explore the brain through the squamous temporal. It is very important to make a large opening in the dura and skull on account of the adjacent encephalitis, which, unless decompressed, will maintain of intracranial pressure and thereby favor extension of brain infection. In the case of temporosphenoidal abscess it is not sufficient to remove merely the roof of the tympanum and antrum. Part of the squamous temporal should be removed as well. For similar reasons cerebellar abscesses, unless very small, should be drained behind or through the lateral sinus as well as internal to it. A cerebellar abscess is much easier to miss than a cerebral abscess, and many elude the most thorough search.

Raynaud's Disease.—L. de Gennes and P. Isaac-Gorges (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris,* March 11, 1926) report a case in which the restriction of the manifestations to certain fingers could be traced to prolonged, occupational local irritation. The patient, a woman of forty-two years, had had since childhood a tendency to pallor and coldness of the fingertips. Ten days previous to admission to a hospital she had begun to have, in conjunction with a slight infectious upset with arthralgia from which she soon recovered, attacks of severe pain and paresthesias in the hands with cyanosis and coldness of the fingers. These attacks lasted about ten minutes, and in the intervals there was numbness of the finger-tips and some darting pains. Gradually the paroxysms gave way to a continuous state of acrocyanosis, numbness and pain. Later symmetrical localizations of gangrene developed in the two hands. The thumbs were unaffected, the tips of the ring fingers presented only a small black area; the middle fingers showed somewhat larger lesions, while the most extensive gangrene affected the little and especially the index fingers, in which all of the palmar aspect of the distal phalanges was involved. There was no evidence of syphilis. Diathermy twice daily brought much relief from the pain and acrocyanosis, but had no perceptible effect on the gangrenous process. Some eruptions apparently of trophic origin appeared on the legs. It was concluded that the gangrene of the finger-tips could not be solely due to vascular spasm. An excised bit of tissue showed pronounced changes in the arterioles of the skin. The localization of the process in certain fingers was ascribed to the patient's factory occupation in which a thin stream of soap suds constantly moistened the index and middle fingers, while the thumbs and other fingers were folded under and not reached by the fluid.

Fractures of Malar Bone and Zygomatic Arch.—J. R. Garner (*International Journal of Medicine and Surgery,* Vol. XXXVIII, No. 11) offers an operation for reducing fractures of this kind and replacing the malar bone without resorting to open operation with its attendant disfiguring scar. The approach is made through the mouth. The patient is anesthetized and the operation proceeds in the following manner:

The entire right side of the face, including the lips, was treated with iodin and then neutralized with alcohol; an assistant next elevated the upper lip and retracted it, so as to expose the sulcus formed by the reflection of the mucous membrane of the mouth from the inner side of the cheek to the gums. This area was also treated with half strength iodin, and an incision not more than one-half an inch in length made parallel with the alveolar process and extending through the mucous membrane down to the buccinator muscle. This incision was about on a line with the first molar tooth. While the assistant held the incised area exposed, the incision was first swabbed out with half strength iodin, and then the tip of a closed pair of stout curved hemostats was introduced and forced gently between the fibers of the buccinator muscle and carried gently up to the lower margin of the malar bone, being guided by the hand on the outside of the cheek. When the end of the instrument was felt to impinge on the malar bone, it was depressed and gently forced backward and upward behind the bone. Care had been taken during the entire introduction and passage of the forceps that no part of the shaft came into contact with the lip or mouth of the patient. Having passed the tip of the forceps behind the malar bone, pressure was exerted upon the forceps so as to raise the bone slightly, and while held in this raised position by the forceps, the malar bone was manipulated into position by the operator's hand on the outside of the face. Upon releasing the pressure on the forceps and pressing the bone back it was found readily to assume its normal position and showed no tendency to recurrence of the displacement. The forceps were next withdrawn from behind the malar bone, and by changing the position only slightly, made to pass in a similar manner behind the depressed zygomatic arch, which was brought back into proper position by the same manipulations used in connection with the malar bone. The forceps were then withdrawn, the field of operation cleansed and the small wound allowed to granulate without suture. A drain was not used. The patient was placed on liquid diet for three days and then cautioned to eat only on the other side of the mouth for a few days longer. An alkaline mouth wash was ordered and persisted in at frequent intervals for the first week.

It is needless to state that asepsis is the keynote to success in this operation. There are no structures in the zygomatic fossa which are likely to be injured if a blunt instrument is used and only a very limited amount of pressure exerted in introducing it. The operation offers a very ready means of access to both the malar bone and the zygoma, and, all other things being equal, from a cosmetic standpoint is far superior to any procedure requiring incision through the skin of the face.

Intracranial Hemorrhage in Newborn.—W. Sharpe and A. S. Maclaire (*Surgery, Gynecology and Obstetrics,* Vol. XLI, No. 5) discuss a series of cases in which the following technic was employed:

A lumbar puncture needle of the size and caliber of the ordinary intramuscular needle was inserted into the fourth lumbar interspace—the baby being flexed in the horizontal position by a nurse so that the head and knees were approximated, and care was taken to have the spinal canal and the median line of the head on a level and parallel with the table. Upon entering the subarachnoid space successfully, the small rubber tube attached to the spinal mercurial manometer was connected with the puncture needle and a careful reading of the pressure was made, the child being quiet and the acute anterior flexion of its body being relaxed. The opening of a stopcock on the needle now permitted cerebrospinal fluid to escape into a sterile test tube. The character of the fluid was noted and if clear and under normal pressure (four to eight millimeters), two cubic centimeters for laboratory examination were drained into the test tube. If under increased pressure (above eight millimeters) and especially if bloody, blood-tinged, or yellow, then an amount was allowed to escape slowly until the pressure registered by the manimeter became normal, care being taken not to permit the fluid to escape rapidly in a quantity large enough to lower the pressure below normal. Thus it was possible to estimate accurately just how much fluid could be drained safely and with no danger of medullary pressure or vascular complications. If the fluid was bloody to any degree, then an immediate second puncture was performed in the third lumbar interspace merely to confirm the presence of blood in the cerebrospinal fluid of the first puncture. Blood due to the puncture itself, technically, is differentiated by the fact that this extraneous blood streaks the cerebrospinal fluid as it drips from the needle and is not homogeneously mixed throughout the cerebrospinal fluid in the test tube; besides, the second lumbar puncture is another control of the findings, both of the blood and pressure as disclosed. According to the pressure and blood consistency of the cerebrospinal fluid, a lumbar puncture of spinal drainage was performed in our first series every twenty-four hours until the cerebrospinal fluid became clear and under normal pressure. In the later series, however, the interval between drainage punctures was made every twelve to twenty-four hours, and in the last series of test cases, a puncture of spinal drainage was being considered even as frequently as every six hours, according to the pressure and the blood consistency of the cerebrospinal fluid. That is, the method of lumbar puncture was used not only as a means of diagnosis, but more as an active method of drainage of the free blood in the cerebrospinal fluid in the hope that clotting of this free blood could be entirely avoided, so that there would not remain unabsorbed any hemorrhagic clot and thus possible organization residue and future blockage of the normal absorption of the cerebrospinal fluid.

Lumbosacral Region and Sciatic Pain.—M. S. Danfort and P. D. Wilson (*Journal of Bone and Joint Surgery,* January, 1925) present a series of cases upon which they comment as follows:

The clinical examinations of the backs show that in all these cases there was evidence of disturbance in the region of the lower lumbar spine. In the majority of the cases this was substantiated by röntgenological examination. Clinical evidence of nerve involvement was found in over half the cases. In many of the cases signs were present which helped to localize the portion of the nerve affected. The areas of anesthesia or hyperesthesia, the changes in the reflexes, and the points of tenderness suggest either the fourth or fifth lumbar roots and the first and second sacral roots as the ones involved. In the opinion of the authors, the anatomical studies show that changes occurring at the lumbosacral junction have the greatest possibility of affecting nerve structures. Conditions existing in the intervertebral canal between the fourth and fifth make that the next most likely point for nerve involvement. The solid nature of the sacrum offers little possibility for involvement of the sacral nerves during their exit, and the subsequent course of these nerves is such as to render their involvement unlikely. They have approached the subject of sciatic pain from four different viewpoints: first, anatomical dissections; second, clinical examination of the spine; third, neurological. examination for localizing evidence; and fourth, röntgenological examination. They believe that the evidence obtained in all the investigations indicates that sciatic pain of the type studied is a symptom of disturbance in the lower lumbar spine and that the site of the lesion is most frequently the lumbosacral junction, and the nerve chiefly involved is the fifth lumbar.

GASTROINTESTINAL

Rectal Cancer.—J. M. Lynch (*American Journal of Surgery,* Vol. XL, No. 2) finds the following procedure the most satisfactory. An incision is made from the back of the anus to the sacrococcygeal joint. The coccyx is removed and the bowel is separated from the sacrum as high as the promontory. The patient is then changed to the recumbent position; the abdomen opened; both leaves of the mesentery are cut; the superior hemorrhoidal is tied, and the tumor, with the glands and fat, is separated by dissection; the anterior rectal wall is separated; the lateral ligaments are clamped and tied. At this stage one of two procedures can be chosen: 1, The bowel is divided and the patient left with an artificial anus; the caudal end is packed down in the pelvis; the peritoneal floor is repaired and the abdomen is closed. 2, The bowel is pulled through the posterior opening; the abdominal wound is closed; the tumor is removed from below; the sigmoid is implanted in the anal canal. On three occasions I have removed the bowel from the brim of the pelvis to the anus and six months later implanted the sigmoid at the anal opening.

Abdominal Surgery.—P. K. Gilman (*American Journal of Surgery,* Vol. XL, No. 1) concludes that the advantages of combined nitrous oxid and local anesthesia are striking. Since our manipulations are perforce gentle, shock is largely eliminated. It is not rare for the patient to leave the table with an unchanged blood pressure. The patient is conscious by the time the postoperative toilet is complete. The often distressing and prolonged recoveries of consciousness from ether are eliminated.

As already stated postoperative nausea and vomiting are practically absent, except at times for an immediate small emesis. Bowel paresis and accompanying distension and gas pains are markedly reduced in their frequency of occurrence. Combined anesthesia patients take fluids earlier, may be nourished sooner than the ordinary ether patient, convalescence more rapidly and suffer less general postoperative distress.

Duodenal Ulcer and Pulmonary Tuberculosis.—I. R. Lisa (*Surgery, Gynecology and Obstetrics,* Vol. XLI, No. 5) states that while the total number of autopsies (four hundred and sixty-six) upon which this report is based is hardly sufficient to warrant positive final conclusions, the following deductions bearing on the relation of duodenal ulcer to chronic pulmonary tuberculosis may be drawn from this review of cases.

1. Duodenal ulcer is found at autopsy more frequently with pulmonary tuberculosis than with any other disease.
2. The ulcer is usually non-tuberculous in character.
3. Pulmonary tuberculosis associated with duodenal ulcer is of usually chronic form.
4. The age of most frequent occurrence of ulcer is twenty-five to thirty-five years.
5. Careful gastric histories in cases of pulmonary tuberculosis, checked by radiological findings, will probably reveal duodenal ulcer in a greater number of cases than is now diagnosed.

Anorectal Fistula.—C. F. Martin (*American Journal of Surgery,* Vol. XXXIX, No. 12) emphasizes the point that every pararectal abscess potentially is a fistula, as it becomes a fistula the moment the abscess either is incised or ruptures spontaneously. Unless the point of entrance of the infection is located and thoroughly dealt with at this time, a fistula surely will result, no matter how widely the abscess cavity has been drained. A wide excision of the infected area, including a free division of all tissue up to and through the infected crypt is the only logical method for preventing fistula.

The internal opening of a fistula will be found usually at or near the anorectal line, while the position of the external opening or openings will depend upon the lines of extravasation of pus or upon the point or points selected for incomplete surgical drainage.

Between these two points the fistulous tract may be palpated, making the use of a probe confirmatory but not a necessity. A trained finger is more useful than a probe.

Some fistulas may be so tortuous and complicated as to require an x ray picture to gain a clear conception of their direction. It is important that this picture be taken from two or three directions, for a picture taken in only one plane is often misleading. Very satisfactory plates may be obtained if a heavy bismuth paste be injected under little pressure through the tracts. If much bismuth has been injected, it may be removed by syringing with olive oil.

Avoidance of the uneven contour of the rectal outlet is best accomplished by a complete excision of the fistulous tract, including the removal of all surrounding inflammatory masses, which are offshoots of the main tract. All overhanging tissue must be excised, even if it results in a sacrifice of a portion of the sphincteric area, in order to make a scar that will be as flat as possible. This flattened scar will present an even surface for the remaining portion of the sphincter to contract against, giving a surprisingly satisfactory degree of control.

In these extensive cases it is important that, after the primary packing is removed, no other be inserted, as too much packing retards healing and produces distorted scars. The wounds should be cleansed often and only an external pad dressing be employed. I am particularly partial to a moist dressing of boric acid solution with no packing of any description.

I do not advise the excision of fistulas and primary suture as a routine measure, for very few cases are suited to this method. It should be used only in the comparatively short and extremely simple types, where it is possible to completely excise the tract and yet be able to obtain good coaptation of the cut surfaces without undue traction upon the line of suture. Care must be taken to protect the anal apex of the wound to prevent reinfection.

Intestinal Obstruction.—T. G. Orr and R. M. Hadden (*American Journal of Surgery,* Vol. XXXIX, No. 10) after experimenting on dogs to note the effect of administration of chlorides in toxemia, found that similar treatment in humans reduced the operative risk. Patients with acute obstruction of the pylorus and small intestive show typical blood and urine chemical changes which are indicative of the degree of toxemia. Since the fall in chlorides appears to be the chief factor in the chemical changes treatment with chlorides naturally suggests itself. All patients with acute intestinal obstruction should have preliminary treatment with water and sodium chlorid before anesthesia and operation.

In the very toxis cases we have estimated that about one gram of sodium chlorid per kilo of body weight is sufficient for the initial dose. This would be about seventy grams for an average sized person of one hundred fifty pounds. With this should be given two to four liters of water. It is desirable to introduce this salt and water as rapidly as is possible with safety. It may be given by hypodermoclysis, intravenously or by rectum. Proctoclysis is the poorest method in the very ill because the very ill patients retain it poorest and it is often impossible to determine accurately the quantity taken in a given time. The other two methods are effi-

cient, fairly rapid and accurate. Both may be used if necessary. Solutions with strength varying from 0.8 to 3 per cent. may be used under the skin with satisfaction. The stronger the solution the more slowly it should be given. A five per cent. solution may be given slowly in the vein with good results. The continuous intravenous drip of Matas may be used.

After this preliminary treatment the general improvement in the patient is usually noticeable and it is at this time operation may be done.

The preoperative treatment and operation by no means ends the therapy. The water and salt should be resumed immediately following the operation and continued as long as needed. The quantity of chlorid given should be checked by blood and urine chlorid determinations when possible. In the absence of such facilities the general condition of the patient must furnish the evidence. As long as the patient has a dry tongue and thirst, water and sodium chloride are needed.

Lymphaticostomy for Peritonitis.—C. H. Whiteford (*British Journal of Surgery,* Vol. XIII, No. 50) suggests that though no further agreement has as yet been arrived at on the indications for lymphaticostomy, its further trial is desirable.

Identification of the duct may be difficult. In at least thirty per cent. of cases the operator must be prepared to find a duct which does not consist of a large single trunk opening into the subclavian vein.

In recorded cases in which the escaping lymph was sterile, the toxicity of the lymph appears to have been taken for granted. In records of future cases, proof of such toxicity should be given.

Permanent or prolonged obliteration of the lumen of the duct, by complete division or by ligature, appears to accentuate unnecessarily the risk of a flow from the fistula so persistent and profuse that death occurs from starvation. Preservation of the lumen might give the chyle a chance of resuming, in part at least, its original route. Provision should be made during the performance of lymphaticostomy for stopping the loss of chyle without having to perform a further operation on a debilitated patient.

OBSTETRICS AND GYNECOLOGY

Patency of Fallopian Tubes.—S. Seidas (*Surgery, Gynecology and Obstetrics,* Vol. XLI, No. 5) describes a simple method of determining the patency of Fallopian tubes as follows:

Possessing a sphygmomanometer, one requires only a uterine cannula, a tube, and some rubber tubing to complete the outfit. The blood pressure cuff is detached from the sphygmomanometer, and the T tube and cannula assembly connected with it. The bulb is worked in the same manner as when one takes the blood pressure. After the cannula is introduced into the cervix and properly adjusted, the bulb is compressed very gently so that the pressure rises only five to ten points with each compression. After each compression of the bulb the operator pauses a moment to note the rise of the mercury. When the pressure reaches a height sufficient to open the tube (in patent cases) and cause the escape of air into the peritoneal cavity, the mercury begins to drop, and continues to drop, until the pressure becomes equal to the resistance offered by the tube. At that point the mercury remains stationary. The bulb is now compressed again, driving the mercury up from ten to twenty points. When the bulb is released the mercury falls rapidly to its former height or a little lower. Another compression of the bulb causes a repetition of the previous occurrence. We are now confident that the patency of a fallopian tube has been established. Although the first characteristic drop of the mercury is manifest evidence that the tube is open the two additional compressions of the bulb serve the purpose of introducing sufficient air into the peritoneal cavity to elicit the shoulder pain as confirmatory evidence of tubal patency.

So small is the amount of air introduced by this method that the shoulder pain does not appear until after the patient has been up and about for several minutes. This pain, though definite and unmistakable, is so mild that, as a rule, it does not interfere with the patient's customary activities, and disappears entirely within twenty-four hours.

It is understood that the cases thus tested are carefully examined to exclude conditions that contraindicate insufflation, and that strict asepsis is practised throughout the procedure.

A Study of the Tubes and Sterility.—S. H. Geist and M. A. Goldberger (*Surgery, Gynecology and Obstetrics,* Vol. XLI, No. 5) obtain the following results of their study:

1. Variations in the course of the intramural portion of normal tubes may offer a bar to impregnation.
2. Intramural lesions may make the passage of sperma or ova impossible.
3. Intramural lesions may be present with or without closure of the fimbriated extremity.
4. One may get a positive or negative insufflation test in normal tubes.
5. One may get a positive or negative insufflation test in diseased tubes.
6. A positive insufflation test means that tubes are patent to gas under pressure, not necessarily to spermatozoa or ova.
7. It is essential to locate the occlusion in a case with a negative test if any reasonable hope of assistance from operative procedure is to be entertained.

Leucocyte Count in Ectopic Gestation.—L. K. P. Farrar (*Surgery, Gynecology and Obstetrics,* Vol. XLI, No. 5) finds that:

1. In ectopic gestation the leucocyte count fluctuates according to the amount of fresh blood being thrown into the peritoneal cavity and the rate of absorption.
2. The leucocyte count tends to drop quickly to normal as the blood in the peritoneal cavity is absorbed or walled in; forty-eight per cent. of one hundred and fifty cases of ectopic gestation had a normal leucocyte count before operation was performed.
3. The leucocyte count was normal in twenty-nine cases of unruptured tubal pregnancy in which there was no free blood and in forty-three cases of ruptured pregnancy in which the blood was walled in.
4. The leucocyte count was an index in one hundred and fifty cases to the amount of free blood in the peritoneal cavity and the polymorphonuclear leucocyte count was increased markedly only in cases having fresh blood in the pelvis and increased in direct proportion to the amount of recent blood found at the time of operation.
5. The fluctuating leucocyte count together with the moderate elevation of temperature differentiates ectopic gestation from a purulent salpingitis with its more uniformly high leucocyte count and fluctuating temperature.
6. In cases of rupture of tubal pregnancy the steadily rising leucocyte count indicates active bleeding before the fall in the number of red cells or hemoglobin gives warning of the condition.
7. The leucocyte count to be of diagnostic value must be taken at least daily and in critical cases even hourly and used in conjunction with the history and clinical findings in the case.

Differential Diagnosis in Cases of Ectopic Adenomyoma in the Groin.—Willis S. Lemon and Arthut E. Mahle (*Medical Clinics of North America,* January, 1925) report three cases in which the ectopic adenomyomas in the groin were confused with adenopathies of the groin. In the differential diagnosis between these two conditions, there are certain factors relating to ectopic adenomyoma in the groin that makes them characteristic. The most important of these is the fact that such growths have appeared only in women, that they are associated with menstrual disorders, and in two instances there were actual tumor formations within the pelvis. They are sluggish, slow growing tumors of benign character, taking vears to develop, and without disagreeable symptoms, excepting during the menstrual period, when they take upon themselves the same functions that are characteristic of the uterine mucosa. The tumor enlarges and its swelling produces discomfort or real pain; the growth becomes tender to the touch and cysts form as small bluish areas beneath the epithelium. These are not only visible but palpable, and on incision contain blood. A negative characteristic is worthy of consideration. In contradistinction to tumors of the nodes, they are found to appear in areas not occupied by lymph nodes. These characteristics suggest to the examiner that the tumor itself must in some way be related to the uterus, whose mucosa alone has the inherent possibility of periodical engorgement. Such a tumor then must

be composed of tissue derived from, and identical with, the uterine mucosa, and therefore may be classified with the adenomyomas, although in an unusual location for such tumors. This is not surprising, however, inasmuch as ectopic types of adenomyomas have been recorded.

Treatment of Tumors of the Spinal Cord.—Alfred W. Adson (*Northwest Medicine*, July, 1925) says that surgical removal is the only proper treatment for benign tumors of the spinal cord. Radium treatment may be of slight palliative value for malignant lesions or angiomas, but too much should not be expected. Intramedullary tumors are the most difficult to treat, since they do not permit reaction, most of them being extensive, infiltrating gliomas. The procedure usually carried out in their treatment is splitting of the cord dorsally, permitting the tumor to extrude spontaneously. Usually this brings about temporary improvement, and in an occasional case permanent improvement may result. It is unwise to attempt removal of an angioma, since decompression in conjunction with the use of intensive radiotherapy is probably the most effective form of treatment. Ependymal cell glioma in the filum terminale can be resected, provided there has not been an erosion through the spinal canal into the soft tissues.

Theoretical Basis of Synergistic Obstetrical Anesthesia and Its Practical Significance.—E. Vogt (*Zentralblatt für Gynäkologie*, January 9, 1926) advises the following technic:

The treatment begins with an intramuscular injection of two c. c. of a fifty per cent. solution of sterile magnesium sulphate together with 0.006 gm. morphine in one syringe. Special ampules have been manufactured for this purpose. The injection of morphine should not be repeated, but the injection of the magnesium sulphate solution may be repeated two or three times if the quieting effect of the first injection is not sufficient or disappears too soon. One hour later a rectal injection of an etheroil mixture is given. Both the ether and the oil should be of the purest quality. Up to two gm. of quinine may be given to offset the paralytic action of the three narcotics on the uterus. Bromides are preferred because of their solubility. Only enough alcohol is added to keep the quinine in solution. The addition of the alcohol also prevents the too rapid diffusion of the ether fumes and the resulting overdosage. The following etheroil mixture is recommended: Quinin hydrobromide, 0.6 gm.; alcohol, 8.0 c. c.; sulphuric ether for anesthesia, 70 c. c.; and olive oil up to 120 c. c.

The patient must be kept isolated and absolutely quiet. The mixture is injected into the rectum through a Nelaton catheter during an interval of the labor pains. The patient is kept in the left posture and a wad of cotton is kept against the rectum with the nates compressed to prevent the escape of the mixture.

The points of practical importance of synergistic obstetric anesthesia are summed up as follows:

1. The contraindications include diabetes, eclampsia without convulsions, jaundice of pregnancy and severe eclampsia, and also diseases of the respiratory tract and the lung, the liver and kidney; also circulatory disturbances and inflammatory changes in the colon, especially in the rectum, and fecal incontinence.

2. The cases suitable for this form of anesthesia are only those in which the previous course of the pregnancy was smooth and those in which a further smooth course is expected.

3. The duration of the anesthesia is about four hours.

4. In primiparæ the anesthesia is induced when the cervical os is about four to five cm. in diameter, and in multiparæ when the cervical canal admits two fingers.

In almost every case a painless course of the delivery may be achieved up to the appearance of the head. If the synergistic anesthesia does not last sufficiently long, a few drops of ether will aid in protecting the perineum.

6. The author has never observed any serious injuries or sequelae of troublesome nature. The fetal heart sounds remain unaffected, and the infant is born in excellent condition.

7. Weak labor pains, which may appear in the course of the anesthesia, are combated by minimal repeated doses of hypophysin.

8. This method, which requires a continuous, careful supervision by a physician, must not be left in the hands of a midwife. It is, therefore, not suitable for general practice and in the home.

Endoscopy of the Uterus.—Harold F. Seymour (*British Medical Journal*, December 26, 1925) describes a new and quite simple hysteroscope, with which he has been able to see and remove a large fibroid polyp and diagnose a case of fungous endometritis. The difference between the appearance of the mucous membrane of the uterus during menstrual life and after the menopause is striking; in the latter case the membrane is much paler and smoother. He has also been able to bring into view the ostium of a Fallopian tube.

The author believes that endoscopy of the uterus will prove useful in diagnosing the uterine causes of genital bleeding, since it can reveal such lesions as glandular hyperplasia of the endometrium, polypi, retained products of conception, chorionepithelioma, and carcinoma. A piece of tissue can earily be removed for microscopic purposes under direct vision. The diagnostic curettage is often a disappointment. The instrument described and the method of using it gave the advantage of extreme simplicity. It is of great value both diagnostically and therapeutically.

Differential Diagnosis Between the Kidney of Pregnancy and Chronic Nephritis in Pregnancy and Between Eclampsia and True Uremia.—Th. Heynemann (*Zentralblatt für Gynäkologie*, October 10, 1925) calls attention to the fact, in general, the diagnosis of chronic nephritis in pregnancy is made much too often. A high rise of blood pressure, red blood cells in the urine and albuminuric retinitis, which has even to the present time been considered as proof of the existence of a chronic nephritis, are found to the very same extent in the kidney of pregnancy. With the appearance of kidney symptoms the diagnosis of kidney of pregnancy should be made only in the late months of pregnancy until the contrary is proved, especially, when eclampsia or the kidney of pregnancy has already preceded it, when a twin pregnancy exists, or when the pregnant woman is a primipara.

On the other hand, the existence of a chronic kidney disease in pregnancy should be assumed to exist in the presence of symptoms of a pronounced renal disease early in the first three to four months of pregnancy, in so far as a hydatid mole does not exist or eclampsia or a kidney of pregnancy has not already preceded during former pregnancies.

The absence of hematuria and increased blood pressure speak in favor of a kidney of pregnancy, but hypertrophy of the left ventricle, on the other hand, speak in favor of a chronic nephritis or sclerosis, especially, when there are other symptoms pointing toward the vascular system. In this connection, albuminuric retinitis, marked headache and marked rises in blood pressure acquire a certain significance.

Furthermore, according to ophthalmologists, the occurrence of certain changes in the bloodvessels of the background of the eye speak in favor of chronic nephritis at the very beginning of the retinitis. Personally, the author has no experience in this respect. But its occurrence even in the recurrent kidney of pregnancy must be borne in mind.

The previous history must be given special consideration in regard to the occurrence of renal diseases. The occurrence of such especially during pregnancy speak strongly in favor of recurrent kidney of pregnancy, but whene they occur outside of pregnancy they speak more in favor of glomerulonephritis. The statements of the patient must be considered very critically. The physicians who treat these cases and hospitals should by all means be consulted as to their knowledge of these patients.

Menstruation.—S. D. Ludlum and E. McDonald (*Surgery, Gynecology and Obstetrics*, Vol. XLI, No. 5) conclude from their study that menstruation is a time of vagotonia or vagus stimulation and that this can be shown in the smooth muscle reaction of the intestine as pictured by the x ray. The wave of vagus preponderance begins from eight to two days before menstruation, reaches its height during menstruation and returns to the intermenstrual condition from three to six days after menstruation. There is some evidence that among other factors this vagus preponderance is, in part, at least, due to the accumulation of calcium in the blood and tissues and that calcium is cast off at the time of menstruation. It is possible that some of the preliminary pains of menstruation are due to intestinal cramps from vagus stimulation. Drugs and salts which reduce the vagus stimulation relieve the menstrual pain.

Medicolegal Notes.

TRAUMATIC ORIGIN OF INFECTION HELD NOT SHOWN

In an action on an accident insurance policy, providing that the insurer would not be liable for infection unless introduced through an open wound caused by external violent and accidental means, which wound must be visible to the naked eye, the Kentucky Court of Appeals holds, Bahre v. Travelers' Protective Assn. of America, 277 S. W. 467, that if the infection was introduced by means of a bruise or other traumatic injury which did not manifest itself for over a week, and there was no open wound visible to the naked eye, the injury would not be compensable under the terms of the policy.

It was also held that evidence of the only physician who testified that an infection of the insured's thigh might have resulted from a bruise or injury received a few days before he saw the insured or might have been the result of an infection he had years ago would not authorize a verdict for the plaintiff, a jury not being permitted to speculate upon the verdict.

In this proceeding, the evidence of the medical experts as to the condition of the deceased's skull at the time of the autopsy, and the presence therein of the fracture and the two hemorrhages, the extent and character of these hemorrhages, and their origin and cause, and their probable effect upon the deceased, and whether they, or either of them, were sufficient to produce death, dealt entirely with matters with which only medical men are familiar, and concerning which they alone could give any intelligent information to the Commission. This evidence, being uncontradicted, was binding upon the Commission, and, according to the above rule, the latter could not reject the same and act upon their own knowledge.

It was held, however, that, under the facts in evidence before the Commission, the opinion of the doctors that the stroke occurred prior to the fall was mere conjecture on their part and not based upon any evidence warranting such a conclusion, there being nothing to show that the pontine hemorrhage could not have occurred immediately following the fall or during the hour during which the deceased lived after receiving the blow from the fall. The courts conclusion therefore was that the Commission was not bound by the opinion of the medical experts that the proximate cause of the deceased's death was the stroke of apoplexy.

There was, however, no evidence from any source to indicate that the death of the deceased was due to the fall, and the burden of proof was upon the applicant for compensation to show that the injury arose out of as well as in the course of the employment.

Moreover, if the evidence before the Commission was insufficient to justify the expert witnesses in concluding that apoplexy was the proximate cause of the death, the court thought that for like reasons it was insufficient to justify a conclusion on the part of the Commission that death was due to the fall, uninfluenced and uninduced by the stroke of apoplexy. With the evidence in such a state, any opinion as to the proximate cause of the death of deceased was held to be a mere surmise and conjecture and not based upon any foundation sufficient to support a warrant of fact. The evidence being considered insufficient to support it, the award was annulled.

FILING REPORT BY PHYSICIAN UNDER WORKMEN'S COMPENSATION ACT—FAILURE DOES NOT AFFECT PHYSICIAN'S RIGHT TO RECOVER FROM EMPLOYER

The New York Appellate Division holds, Landberg v. Seymour Dress Co., 212 N. Y. Supp., 432, that, "under section 13 of the Workmen's Compensation Law, no claim for medical or surgical treatment is enforceable except 1, as incidental to, or a part of, an award to an injured employee, and 2, unless, within 20 days following the first treatment, the physician or surgeon furnishing the treatment shall furnish to the employer and the Industrial Board a report of the injury and treatment on a form prescribed by the Industrial Board. This applies to every claim by a physician or surgeon for services rendered to an injured employee, payment of which is sought through an award by the Industrial Board, and whether employed by the employer or employee. This, of course, has no application to the right of a physician or surgeon to recover in an action at law from the employer for services rendered at his request."

EVIDENCE ESTABLISHING TESTAMENTARY CAPACITY

The New York Appellate Division holds, In re Delmar's Will, 214 App. Div., 500, 212 N. Y. Supp., 456, that the testimony, on the issue of testamentary capacity, of a physician who gave his answers as to the testatrix's condition and ability to comprehend the nature of her act to a hypothetical question, and who had never seen the patient, had not attended similar cases for over 25 years, and admitted that the testatrix might have been able to understand the simple bequests, but not the disposition of the residue, did not rise to the probative weight necessary to overcome the testimony, offered by the proponent of the will, of the doctor who attended her, the attorney who made the will, and another witness who was present, which testimony bore all the earmarks of credible statement, and carried conviction by its inherent probability.

ALLEGED FAILURE BY HOSPITAL TO USE X RAY IN DIAGNOSIS IS CAUSE OF ACTION EX DELICTO UNDER CALIFORNIA STATUTE

The Circuit Court of Appeals, Ninth Circuit, holds, Chalmers v. Southern Pacific, 8 F (2d) 480, that an action against a railroad company which maintained a hospital for the care of its injured employees, which alleged that the defendant, in violation of its contract, refused to use the x ray to diagnose a fractured vertebra, was not an action on contract, but an action in tort within the meaning of the California statute of limitations, Cal. Civ. Proc., sec. 340, subd. 3, requiring action to be brought within one year.

WHEN PRESUMPTION AGAINST SUICIDE MAY PREVAIL

Where the cause of one's death is unexplained or undisclosed by evidence, or where evidence tending to prove self-destruction is contradicted or impeached, or some evidence adduced is consistent with a reasonable hypothesis that the death was not self-caused, the presumption against suicide or self-destruction may prevail. But such presumption cannot properly prevail where uncontroverted evidence, whether direct or circumstantial, shows how the death was caused and that it was self-inflicted, and not by accident or the act of another. New York Life Ins. Co. v. Weaver, C. C. A., 5th circ., 8 F (2d), 680.

VERIFICATION OF X RAY PICTURES

The New York Appellate Division holds, Vincent v. Otis Elevator Co., 212 N. Y. Supp. 76, that a finding of the State Industrial Board that a claimant at the date of the accident was suffering from a tubercular condition, which became activated by the accidental injury, based upon certain notes interpreting x ray pictures made by a physician who was not called to verify the pictures or the notes, was grounded upon other than legal evidence, necessitating the reversal of the award.

VOL. CXXIV, No. 4 NEW YORK, WEDNESDAY, AUGUST 18, 1926 WHOLE No. 2335

Concerning the Nature of Malignancy*

J. GEORGE ADAMI, C.B.E., M.D., F.R.S.

Vice Chancellor of the University of Liverpool

Liverpool

It is as a pathologist that I have been invited to open this discussion. I doubt whether I can perform a greater service than that of directing your thoughts to the nature of malignancy or, more broadly, to certain general principles underlying disordered and excessive cell growth. And this because once again the belief in a specific or unitarian microbic origin of cancer is gaining force and increasing acceptance.

I admit that there is much that is attractive in the theory of the specific nature of cancer: I am old enough to have been taught that phthisis was due to the tubercular diathesis, to a defect of constitution, and that malaria, on the other hand, was miasmatic, brought about by particular states of the atmosphere, and thus have experienced the revulsion in attitude, and what is more to the point, clearing in outlook and increased mastery over disease that has followed the discovery and universal acknowledgment of the essential microbic factor in both of these greater afflictions of humanity. I can wholly sympathize, therefore, with the longing to accomplish for this other foremost affliction what has been achieved for tuberculosis and malaria. For if now after forty years and more since the discovery of the tubercle bacillus we are still groping after, without having surely achieved, methods of immunity and of cure, based upon our knowledge of the properties of that bacillus, no one can venture to deny that the knowledge of those properties has placed our understanding of the disease and of its treatment upon a wholly different plane. It has raised that treatment from the empiric to the scientific level.

Were it possible for us to discover the germ of cancer then this same advance to a higher plane would be brought about. It is but human that earnest hope should inspire belief, and this all the more when over and above hope there are certain facts which, so far as they go, support the assumption.

I am not going to detail all those facts: the more outstanding will suffice for the present purpose. There is in the first place the fact that while the more virulent bacteria growing in the body lead to cell necrosis and destruction, less virulent strains of the same bacteria together with other less virulent bacteria stimulate cell growth. That growth, it is true, as observed in general only continues so long as the bacteria which cause it remain alive and multiplying: it ceases and undergoes retrogression and absorption with the death and disappearance of the causative microorganisms. In general it does not become malignant, that is to say, autonomous, continuous of itself when once started. Possibly here our conception of what constitutes malignancy may be wrong. It may be more correct to say that thus far we do not regard as malignant a local growth of cells of any order which recedes and disappears with the death of the microorganism which has induced it, or again that progressive growth is a feature of malignancy.

Passing, however, beyond these more general considerations, there are certain fully established cases in which microbes are known to be directly associated with the development of definitely malignant growths. The first in order of time and of completeness of detail has, it is true, to do not with animal but with vegetable growths, namely Erwin F. Smith's long continued and most thorough studies upon the crown galls which affect many flowering plants. From these he has isolated a bacillus, the Bacillus tumefaciens, has grown it for years in pure culture, and inoculating it into a variety of plants has produced most often purely cellular tumors, undifferentiated and of sarcomatous type, capable of forming by direct extension what in the absence of blood and lymphatic vessels may almost be termed metastases (for in their mode of growth by such direct extension they are comparable with the secondary growths seen, for example, around a mammary cancer). But if the inoculation be made in the neighborhood of growing points, more complicated organoid or teratoid tumors may be produced, with development of irregular and multiple aerial roots, twigs and leaves. I have personally studied these crown galls and can find no valid departure in them from what we accept as malignant growths in animals. The only point about them which is not yet to my mind fully established is whether when active growth is once started it can continue independently, that is to say without the continued intracellular multiplication of the bacilli. There are indications, particularly in the teratoid

*An address opening the discussion upon Cancer, at the Annual Meeting of the Royal Institute of Public Health, Bristol, May 21, 1926.

Copyright, 1926, by A. R. Elliott Publishing Company.

forms that this is so. The main point is that herein we have evidence of the existence of a bacterial species capable of originating a progressive, invasive and malignant growth.

The other outstanding case is, I need scarce remind you, that of chicken sarcoma with its ultramicroscopic filterable virus which, first studied by Rous in New York and independently confirmed by the discovery of another strain by Tytler, now of Cardiff, and others, has been the primary subject of the remarkable investigations by Gye and Barnard which are creating so much interest at the present moment.

The main feature differentiating this from all forms of transmissible malignant tumors in animals hitherto studied is this, that whereas all those other tumors are transmitted by grafting and so represent the continued progressive growth of the tumor cells in series from animal to animal, here, as in Erwin F. Smith's crown gall in plants, a tumor of sarcomatous type originates *de novo* in the individual inoculated with the virus, without grafting, and without transmission of the tumor cells of the other individual. It originates obviously through the proliferative stimulus exerted by the filterable virus under certain conditions upon the connective tissue cells of the inoculated animal. It is true that the tumor so induced is not a cancer proper: it is a sarcoma and not a carcinoma, and I have not a little sympathy with Dr. John Brown who this afternoon is going to urge a reversion to the older and sharper distinction between cancer proper and sarcoma. It is true also that not a few pathologists support Dr. Brown in regarding sarcomas as coming into a different category from carcinomas proper, holding them to pass by imperceptible gradations into the granulomas or inflammatory new growths. But it is equally true that the chicken sarcoma fulfills all the usually accepted criteria of malignancy: it is progressive, invasive, infiltrating and destroying the normal tissue cells of the part, and capable of giving rise to metastatic growths—at a distance.

With these striking examples before us it is not unnatural that there are many today who jump to the generalization that all primary malignant growths of all orders originating in the tissues of man and the higher animals are of microbic origin, aye and some who go so far as to hold that one common filterable virus is responsible for the genesis of all malignant growths throughout the animal world.

Now as a general pathologist it is my duty to state as emphatically today as I did twenty-five years ago that no one who has made a broad study of neoplasia, of all the varieties of new growths, both innocent and malignant, affecting mankind and the higher animals, can for one moment support either of these theses, neither the first nor, still less, the second. Time and considerations for your wellbeing forbid that I should place before you the full argument. I remember that it took me the better part of an hour and a half to develop it before the Yale University Medical Society. Rereading that address, I am impressed by the fact that, barring the absence of certain more "modern instances" which would yet further strengthen it, it is as valid, and I trust as convincing, as if it had been written within the last few months. You will find it in full in the *British Medical Journal* of March 16, 1901, in résumé.

1. Neither histologically nor clinically can any precise demarcation be made between benign and malignant growths: a growth so well differentiated and so benign as a chondroma may nevertheless have metastases: and a fibroadenoma of the mammary gland may pass imperceptibly into the carcinomatous state.

2. Time and again the pathologist finds it impossible to state whether he is dealing with a benign or a malignant growth. In other words there exists no absolute demarcation between the one and the other condition: histologicaly there is no constant tissue change to indicate that some new factor has come into play, bringing about a change in the nature of the growth, save the obvious invasion of the immediately surrounding tissue. Nor is it an exaggeration to say that all benign growths may take on malignancy.

But now these benign growths are of very different orders. If we attempt rapidly to classify them we find that they come under the following groups: First there are the teratomas. These teratomas represent the attempted and perverted growth of one individual within the tissues of another individual, either as fetal inclusions, in which during fetal life the feebler of a pair of twins becomes caught up into the body of the stronger, or by serial deduplication, as when from either the anterior or posterior growing point certain totipotential cells take on independent growth and produce a mass of tissues of various orders, projecting from the base of the skull through the mouth, or at the other end forming a coccygeal teratoma. These we may speak of as *twin teratomas,* as distinct from the *filial teratomas* in which, as in ovarian dermoids, totipotential germ cells without fertilization take on independent and parthenogenetic growth and produce a jumble of various tissues, and this often long years before the attainment of sexual maturity. If the Duke of Wellington spoke of his son, the Marquis of Douro, as a "damned parody," *a fortiori* may these growths be given that appellation.

These teratomas originate from what the morphologist Barfurth has termed *totipotential* cells, either from germ cells, which as such are capable of giving origin to tissues of all orders, or from cells, such as those of the growing points of the embryo, which have become so little differentiated that they still retain like properties.

Closely allied to these are the *teratoblastomas,* derived from cells of the growing embryo which are *multipotential,* i. e., which in the course of development have lost the power of giving origin to tissues of all orders, but which nevertheless have the power of giving origin to tissues of several orders. There are, for example, certain tumors of the kidney region, composed of kidney tubules, and cords of cells resembling the first stage of the uriniferous tubules, of muscle fibres, and even of bone, evidently derived from cells of the dorsal metameres which under normal conditions might have undergone division and differentiation into vertebral, muscular and renal elements, which becoming displaced, continue an independent existence and sooner or later give rise to a jumbled mass of all these tissues.

This leads on to the third main group, the *blastomas* proper, comprising the bulk of what I may term ordinary tumors, tumors whose predominant element, as I have elsewhere pointed out, is formed of cells which in the course of development and differentiation have

become *unipotential,* capable of giving rise to one order of tissue only, be it of connective tissue type, as for example fibrous tissue (as in the fibroma), cartilaginous (as in the chondroma), or epithelial (as in the various orders of epithelioma and adenoma). And this either in the fully differentiated form, when the tumors most often are benign, or in various stages of dedifferentiation and persistence in or reversion to the vegetative or embryonic type, and then it is that we deal with malignant tumors, sarcomas and carcinomas.

As I pointed out at the International Congress of Medicine in London in 1913 there is yet another order of excessive growth of particular tissues that deserves consideration in this association, the remarkable group of what I have called the *hyperblastoses,* conditions in which individual tissues undergo diffuse relative overgrowth. Once I mention these, you will recall how they exhibit features in common. There is, for example, adiposis dolorosa, or Dercum's disease, in which there is excessive development of the fatty tissue; acromegaly, with its striking overgrowth of the bony skeleton; and gliomatosis, with its diffuse overgrowth of the neuroglia. With these may, I think, be placed such conditions as neurofibromatosis multiplex or Recklinghausen's disease, and multiple ecchondroses together with the various forms of leucemia. The feature about all of these is that while they tend to be diffuse they are not universal. They affect the particular tissue in particular parts of the body, acromegaly, for example, not all bones but the bones of the cranium and the extremities, adiposis the fatty tissue of the back of the neck, it may be, or the buttocks, or the abdomen more particularly. And for our purposes quite the most important feature is that in the outstanding examples of the condition we clearly have to deal with disturbances of the endocrine functions as essential factors—in acromegaly with pituitary disturbance; in some forms of adiposis the pituitary is also involved, in other forms, as in Dercum's disease, administration of thyroid leads to resorption of the fatty growths.

Now as pathologists surveying the whole field we have to ask:

1. Can we recognize a common origin for all these various orders of growth?

2. Is the assumption of malignancy confined to any one order, or may it present itself in all?

3. Can we detect any clinical signs, or histologically any local irritative or other signs indicating the introduction of a new factor in the passage from the benign to the malignant state?

1. On the face of it, after the classification just given, the answer to the first question must be in the negative, when some tumors, like the teratomas, represent the attempted growth of one individual within the tissues of another, and others represent the aberrant growth of individual tissues of the individual himself. Probing deeper into the matter, however, we seem to see that one and all are the outcome of cells that are out of place. Not that all cells out of place—embryonic cellrests or the irregular proliferations set up by irritation, necessarily give origin to tumors, but that the condition of out of placedness, or heterotopia, is a necessary antecedent to tumor growth.

2. The answer to the second question is more clear cut. Any and every order of tumor is capable of manifesting malignancy. Malignancy is not confined to the blastomas proper. Certain teratoblastomas, notably the compound renal tumors, are extraordinarily malignant; frequent in early childhood, the indications are that in some cases they begin development before birth, and this with no evidence of malignancy in the mother. The most intensely malignant tumor of all is not a blastoma proper, but a grafter tumor, what we may term a teratoid blastoma, the deciduoma or chorioepithelioma malignum, derived from, in fact entirely constituted of the trophoblastic outer layer of the chorion of the embryo. As I pointed out in 1902, the choroidal epithelium is naturally, or physiologically, malignant. To secure nutriment for itself and for the embryo of which it is a part, it exhibits a tropism, sending out processes which invade and erode the maternal tissues until they reach and penetrate the uterine blood sinuses, there absorbing food which is carried by the capillaries of the chorionic villi to the growing embryo. When abortion takes place, and only then, and apparently only when abortion takes place before these outer trophoblastic cells are worn out and disappear, then it may happen that, as I have elsewhere expressed it, the habit of work being interrupted becomes replaced by the habit of growth, and these decidual cells being well fed multiply in the maternal blood sinuses, fill them, and carried to the heart and the lungs multiply there, becoming rapidly fatal. As Professor Blair Bell has very acutely pointed out, here is an example, not of prior dedifferentiation, but of persistence of properties. Here, it seems to me, is the crucial case. Do we need to postulate the presence of germs to stimulate cells to carry out their normal functions? If so, then logically speaking we must demand the presence of germs to explain the development of twins, because the fraternal teratoma is only a twin gone wrong. And indeed we must predicate the beneficent action of germs to bring about the fertilization of the ovum, and the proliferation of the ultramicroscopic microbes also. We must thus accept, with the old Manchester poet, John Byrom, that:

> Big fleas have little fleas upon their backs to bite 'em,
> And little fleas still lesser fleas, and so *ad infinitum.*

3. I think, gentlemen, that after this *reductio ad absurdum,* you will admit that it is not necessary for me to answer in full the third question. If cells normally in the vegetative stage, can continue growing and can produce malignant growths, we need not postulate the necessity for the introduction of a new factor to initiate growth in all cases. I have already, you will remember, admitted freely that we possess indubitable cases in which microbes initiate not merely cell growth but malignancy. But this is altogether another matter from saying that one particular order of microbe is concerned in the production of all malignant tumors. That is a wholly untenable proposition.

Time and your patience forbid that I should this afternoon take up the further and most debatable question of why certain cells out of place take on malignant properties while others do not, and that I should enter into the relative parts taken by the growth stimulus affecting certain cells on the one hand, the tissue and body resistance on the other. I shall be satisfied if I have shown you that there is

not one but possibly many factors concerned in malignancy: that all malignant tumors have not a like causation, and that while it is right and proper that we should investigate these various factors, it is unwise to become obsessed with the idea that the solution of the cancer problem is to be reached by proclaiming and by investigating one mode of causation only. And that being so, taking everything into consideration, the wiser and the more fruitful course at the present time is to study not what originates but what ends cancer. Therein I feel convinced that we perform the greater service to humanity. That is why I have consistently interested myself in Coley's work in New York, begun thirty-five years ago, and why now I wholeheartedly support my colleague, Professor Blair Bell, in his employment of colloidal lead. Both workers are devoting their lives to the one object of causing the death and absorption of malignant tumors by the administration of drugs in such a way that, through the blood stream, they reach all the foci of growth scattered through the body. Both acknowledge that surgical removal and radium and x rays are valuable adjuvants, but only adjuvants, since not one of the three methods can surely effect the removal of all metastases. Without in any way holding that we have at last discovered the sure method of arresting cancer in all cases, without in the least believing that in colloid lead Blair Bell has discovered the ideal substance, I nevertheless fervently believe that a huge advance has been made, that, as it were, we have turned over a new page, and that from now onwards medical research will concern itself over the provision of ever better and surer methods of arresting cancerous growth. Therein I fervently believe must lie our foremost hope and our achievement for the good of suffering humanity.

Affections of the Epiphyses Peculiar to the Second Decade*

IRVIN BALENSWEIG, B.S., M.D.
New York

(*Concluded from page* 147)

That of December, 1923, showed the presence of a premature ossification of the epiphyseal line; good reduction of the fragments; diminution of the joint space. That of August, 1924, was similar in all respects to the previous röntgenograph, and in addition shows some irregularity of the head of the femur, plus an outward rotation of the shaft.

Case V.—A. Z., aged thirty-one years; male; was operated upon some sixteen years ago at the Hospital for the Ruptured and Crippled by Dr. R. Whitman for an epiphyseal separation of the left hip of one year duration. He returned because of persistent pain about the hip and knee. Patient states that he remained free from pain for a number of years following the operation.

Examination showed a well developed male of normal weight for his height, walking about without assistance, but with a left hip limp; the limb was maintained in an attitude of flexion and external rotation. Flexion of the hip was possible to a right angle; extension to 170°; abduction for 10°; internal rotation is completely restricted. The affected limb was shorter by one inch. The thigh presents an atrophy of three inches, and the calf one half inch.

The röntgenograph of November, 1924, discloses the presence of a large mushroomed head; short and broad neck; coxa vara deformity. The interarticular space is of normal dimensions. The findings are quite similar to those observed in the late or healed stage of some cases of Perthes' disease.

Vertebral epiphysitis is an affection of the spine occurring during the second decade of life and more especially in females. It is usually insidious in onset and the child is brought by the parent because of either the pain and fatigue complained of or because the school teacher or parent have observed the presence of round shoulders. The patient is not likely to care to play with the other children as much as formerly and is inclined to remain indoors and take to excessive reading in a faulty position thereby aggravating the round shoulders and also bringing on eye strain, etc.

Etiologically the condition is probably a mild epiphyseal infection that is aggravated by weakening of the epiphyses due to excessive growth, overweight and the faulty posture and the superincumbent weight of the spine. The posture may be faulty because of the fatigue and muscle pain thereby forcing the patient to assume the most comfortable position. The subjective symptoms therefore are:

1. Pain either between the shoulders or in the lumbosacral region.
   may be absent in long standing cases.
   In the early stages aggravated by exercise.
   subsides with rest.
2. Fatigue
   more apt to be most severe later in the day.
3. Stiffness
   after sitting.
4. Round back—functional or organic. In the early stages of the affection the curvature is more apt to be functional, but as the condition progresses the deformity becomes fixed and as brought out by Buchman may result in a rotary lateral curvature as well.
5. There is usually found to be an accompanying myositis either due to infection or strain. The muscles most often found to be tender are the rhomboids and trapezii; then the long muscles of the back.

There is tenderness of the spinous processes; on either side of the spine; and occasionally of the crests of the ilia. This latter condition I believe is due to muscle strain or the pull of the muscles on their

*Read before the Harlem Medical Association, February 3, 1926. From the hospital for the Ruptured and Crippled.

points of origin and not to involvement of the epiphyses as no röntgenologic changes have been noted.

Röntgenologic findings—The spine may not reveal any curvature. The epiphyses become enlarged, moth eaten and therefore indistinct. The intervertebral spaces are observed to be cloudy, irregular or diminished. The vertebral outlines frayed and wedged. Later one observes a distinct posterior curvature of the spine and in some few cases a lateral deviation in addition. Lastly there are the stages of regression with a return to normal or progression to osteoarthritis especially if the condition arises during the latter part of the second decade (Buchman).

CASE REPORTS

Case VI.—J. H.; aged sixteen; male, schoolboy. Seen for the first time March 25, 1925, because of

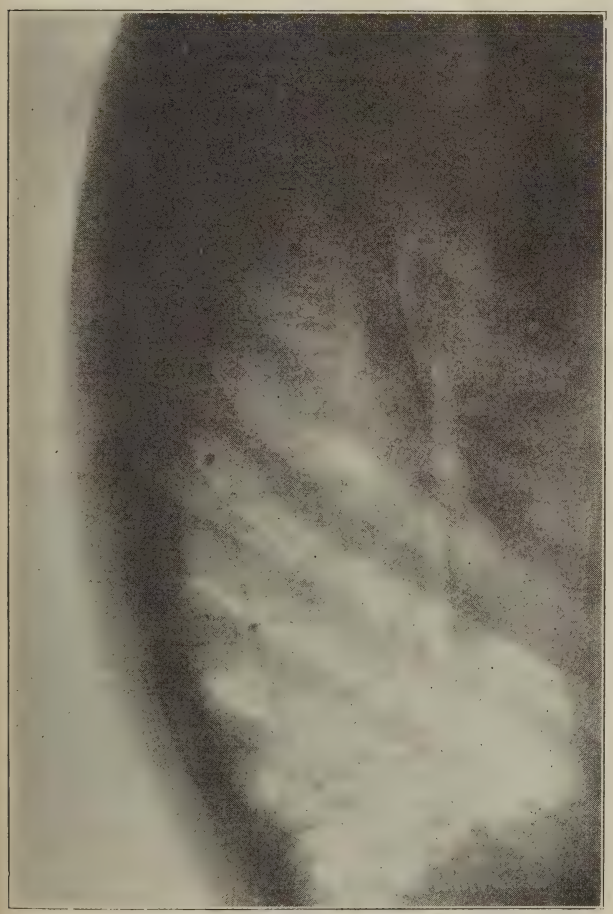

Fig. 7.—Case VII. J. A. Reveals the presence of a round back and irregularity of the dorsal vertebræ due to an epiphysitis.

a curvature of the spine and occasional pain across the lower part of the back. Mother stated that the deformity was first observed one year ago. Patient at the time of onset of the condition complained only of becoming tired rather quickly. Well developed adolescent male of normal weight for height and age, presented a marked posterior curvature of the spine extending from the second dorsal to the second lumbar vertebra with the apex of the curve at the level of the seventh dorsal vertebral spinous process. There was a slight deviation of the lower dorsal spine to the right with a compensatory curve to the left in the lumbar region. The lower extremities were of

Fig. 8.—Case VIII. S. D., röntgenogram of the right knee of March, 1923, showing evidence of disease of the tibial tubercle.

equal length. The röntgenogram of March, 1925, revealed an irregularity of the lower dorsal vertebrae accompanied by wedging resulting in the posterior curvature. The dorsal intervertebral spaces were diminished and irregular. The patient was admitted in the hospital and placed on a convex stretcher frame with traction both to the head and pelvis. Remained on the frame for a month at the end of which time a distinct improvement was noted. The patient was discharged from the hospital wearing a plaster jacket. The plaster jacket was converted into a corset after being worn for two months and the patient instructed to lie on frame during the day and sleep on it at night (the hospital frame and traction apparatus having been removed to the patient's home). The patient's height on his return home had increased two inches. His condition at the end of seven months was quite satisfactory.

Case VII.—J. A.; aged fourteen; male; schoolboy; was first observed August, 1922, because of round shoulders. The mother stated that she noticed the deformity one year ago and that it had been progressing rather rapidly. The patient complained of no pain, but tired easily. Examination disclosed an overgrown boy presenting a moderate round back. The spine was freely movable in all directions. While under observation a slight deviation of the dorsal spine was noted. As a result of this finding the patient was advised to enter the hospital, where he was placed upon a convex stretcher frame. He remained in the hospital for six weeks at the end of which time he was discharged wearing a plaster jacket. The jacket was renewed from time to time and in spite of this form of therapy the curvature became more pronounced. The examination in Feb-

ruary, 1924, revealed the patient to walk quite awkwardly with an elevation of the right shoulder, and an upper right dorsal curvature of the spine. There was also noted a mild compensatory curvature of the lumbar spine to the left. The dorsal curve extended from the fourth to the twelfth dorsal segments with the apex at the level of the seventh dorsal spinous process. The lower extremities were of equal length. March, 1924, a fixation operation of the spine was performed, fusing the articular facets and the spinous processes from the level of the fourth to the eleventh dorsal vertebrae. Final examination October, 1925, showed the patient to walk with the shoulders on equal levels, and the curvature to have been arrested. Result to be considered satisfactory.

The röntgenographs taken during the course of

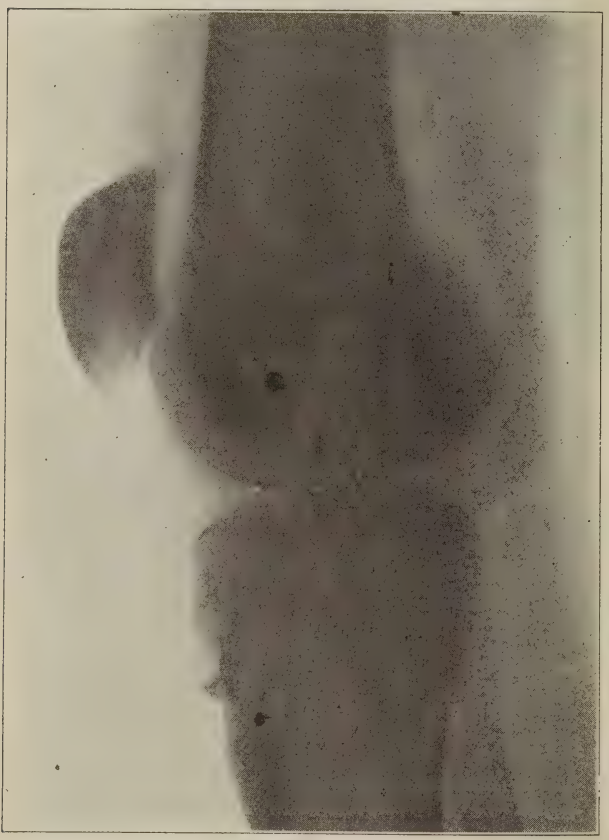

Fig. 9.—Case VIII. S. D., röntgenograph of August, 1924. Disease is healed.

the affection revealed in addition to the curvature a well advanced epiphysitis involving the lower seven dorsal vertebrae.

Osgood-Schlatter disease of the tibial tubercle. Here we are confronted by two distinct types. 1. The common form that appears to be infectious in origin, and occasionally accompanied by a mild traumatism. 2. The infrequent type; that due to a distinct injury and revealing a marked displacement of the entire epiphysis; or a fracture of the epiphysis with separation of the lower fragment. (I have personally never observed an instance that could be classified in this way).

The condition is most frequently observed in males between the ages of ten and seventeen years. M. M. Pomeranz records two instances in females in a series of seventeen cases. About twenty-five per cent. are found to be bilateral.

SYMPTOMS

Onset is insidious. The pain complained of is in the pretibial region; intermittent; worse on going up

Fig. 10—Case XI. E. E., subchondral fragmentation of the epiphyses

and down stairs; relieved by rest. The greatest amount of pain is observed to be during the last few degrees of extension of the knee, and due to the fact that the greatest strain is placed upon the tubercle through the patella tendon at this time. Objectively there may be a limitation in extension to within five to ten degrees of normal. Pretibial swelling; occasional local heat; acute tenderness on direct pressure and when there is a definite history of traumatism, swelling of the knee may be an accompanying symptom. Röntgenologically the lateral view shows: swelling of the soft tissues overlying the tubercle; erosion, cavitation and fragmentation of the epiphy-

Fig. 11.—Case XII. J. H., showing separation of the epiphysis for the lesser femoral trochanter.

sis; haziness of the epiphyseal line; true fracture of the epiphysis; and lastly deposition of lime salts and union of the epiphysis with the diaphysis.

TREATMENT

In the painful type it is often necessary to apply a plaster knee bandage. In the majority of the cases it is sufficient to apply adhesive strappings every other week until the pain subsides. The above may be combined with the administration of diathermia to hasten the healing process.

PROGNOSIS

It is a self-limiting disease lasting from several months to about one and one half years.

CASE REPORTS

CASE VIII.—S. D.; aged fifteen years; male; schoolboy; was first observed March, 1923, because of painful knees of several months' duration. Onset insidious. Pain worse when running or when walking up and down stairs. No history of an injury. Well developed adolescent male walked about unassisted and without a limp. Both knees present a pretibial swelling. Movements of the knees were free and painless excepting during the last few degrees of extension. There was definite local tenderness of the involved regions. Röntgenographically; the left knee in the lateral view showed an indistinct moth eaten area in the location of the tibial tubercle. No evidence of epiphyseal separation. The right knee; cavitation of the entire epiphysis with a thin layer of calcification indicated the anterior border of the epiphysis; thickening of the overlying soft tissues. The pictures were taken at the time of admission to the clinic. Röntgenograms of August, 1923, showed the presence of well formed epiphyses, but they still showed some mottling. Those of August, 1924, showed the disease to be completely healed.

The knees were strapped every other week for a period of some ten months. Although the pain subsided the process according to the röntgenograms did not return to normal until August, 1924, approximately twenty months after the onset of the affection.

CASE IX.—S. S.; aged thirteen; male, schoolboy; was observed July, 1925, because of a painful right knee of two months' duration. No history of an injury. Examination revealed an overgrown boy walking about with a slight right knee limp, and presented in addition to the above a double knock knee deformity and abducted feet. The left knee was negative both clinically and röntgenographically. The right knee presented a pretibial swelling; tenderness of the painful region and pain referred to the above site on arising from a squatting position. The x ray disclosed a small excavated area the size of a pea with an elevation of the periosteum resulting in a cystic formation. The remaining portion of the tubercle was normal in all respects. The overlying soft tissues were thickened. Patient was treated with adhesive strappings for a period of two months with complete cessation of pain.

CASE X.—E. P.; aged thirteen and a half; male; schoolboy; was seen March, 1925, because of a painful left knee of six weeks' duration. There was no history of recent traumatism. The patient presented the findings typical of the condition under discussion but in addition presented an interesting finding; due to an attack of infantile paralysis during infancy the opposite extremity was weak and on x ray the knee it was noted that there was an absence of the tibial tubercle.

This is significant as it tends to show that the tibial tubercle is a strain epiphysis and requires a certain amount of resistance to cause its appearance.

APOPHYSITIS OF THE OS CALCIS

Here we are dealing with an epiphysis that is subject to constant strain as a result of the persistent pull of the tendoachilles. Traumatism, however, in my opinion, plays but a contributory rôle; for we frequently observe children suffering severe traumatisms to both heel and ankle without an accompanying apophysitis; and again we find the affection in those who present no history of an injury.

The affection is observed between the ages of nine and fifteen years. More frequent in boys, and more often bilateral than unilateral. The onset is usually insidious and may have been accompanied by a traumatism. The patient complains of pain about the heel; walks with a slight limp or when acutely painful may be found to walk on the toes. Objectively the heel is tender both laterally and posteriorly. Dorsiflexion of the foot with the knee extended is limited and painful. Röntgenologically the condition resembles Legg's disease of the hip (a subchondral fragmentation of the epiphysis with an occasional disturbance of the juxtaepiphyseal region and cloudiness of the epiphyseal line).

TREATMENT

Strapping of the foot in equinus with an elevation of the heel one half inch. When acutely painful it might be necessary to apply a plaster foot bandage.

PROGNOSIS

A self limiting disease lasting several months.

CASE REPORT

CASE XI.—E. E.; aged nine years and ten months; male; schoolboy; was observed December 29, 1925, because of painful ankles and awkward gait. Duration five months. No history of injury. For the past two months the left heel had been quite painful causing the patient to occasionally walk on the toes of the left foot. Examination: child of normal weight for height and age, walking with both feet in an attitude of persistent abduction. Movements of the ankles were not restricted excepting dorsiflexion of the left foot. The left heel was tender to touch both laterally and posteriorly. The right heel was tender posteriorly over the epiphysis. The röntgen ray findings were indicative of the condition under discussion.

Epiphyseal separation of the lesser femoral trochanter. The causative agent is primarily one of a sudden strain transmitted to the lesser trochanteric epiphysis through the psoas muscle.

SYMPTOMATOLOGY

The injured is usually able to walk about without assistance, but with a hip limp, the thigh being held in slight flexion, adduction or abduction and externally rotated. Pain is present when walking. With the patient on the examining table, swelling, ecchymosis, and point tenderness in the region of the lesser trochanter are occasionally observed; whereas, Lud-

loff's sign is always found, and is pathognomic. (With the patient in the recumbent attitude, partial flexion of the extended limb is possible due to the action of the tensor fasciæ femoris and rectus femoris muscles; with the patient in the sitting position this action cannot be performed because of the inactivity of the psoas muscle.) Passively movements can be carried out in all directions; extension and abduction, however, may be partially restricted and painful.

CASE REPORTS

Case XII.—J. H.; aged sixteen; male; schoolboy. During the act of running on September 29, 1923, he

Fig. 12.—Case XII. J. H., same hip taken several weeks later revealing union of the apposed surfaces.

was seized with a sudden pain in the left groin. As a result of this he had to stop running. Since then the pain had persisted and the patient had been walking with a decided limp. The boy was in good general condition; walked with the aid of a cane, with the body tilted to the left and anteriorly. All motions of the hip were free, excepting flexion, which was impossible of performance with the patient in the sitting position. Passively all movements were free, extension being painful. There were no points of tenderness, no discoloration and no swelling. Measurements of the lower extremities were equal. The röntgenogram showed the scale like epiphysis of the lesser trochanter to be displaced upwards.

A short plaster spica was applied in the walking attitude and maintained in position for one month. Upon removal of the plaster the patient was found to be able to voluntarily flex the extended lower extremity when in the sitting attitude and was therefore discharged as cured.

X ray taken seven weeks after the time of injury showed the presence of union between the apposed surfaces of the fragments.

Case XIII.—G. S.; aged sixteen; male; schoolboy. November 16, 1923, while playing football and running backwards, stopped suddenly in an attempt to catch the ball. This necessitated a lunge to the left with the left leg on the ground and rotated inwards. Felt a sudden pain in the left groin, but continued to play. That same evening while playing kick the hoop, on kicking the hoop rather forcibly with the left foot, suffered a recurrence of the pain, and this time had to be assisted to his home. Walked about the clinic twenty hours later. Examination: well developed boy walking about unassisted but with a decided left hip limp, with the limb rotated outward. Movements were free in all directions excepting flexion; this being impossible both in the supine and sitting positions. There were no points of tenderness, no swelling, no discoloration. Measurements were equal.

Röntgenogram revealed the presence of a separation of the lesser femoral trochanter.

An adhesive plaster hip strapping was applied reinforced with a flannel spica bandage. This was maintained in position for two weeks. When last seen (December 15, 1923) four weeks after the injury, the patient had completely recovered and the x ray showed the presence of callous formation.

Separation of the anterior superior spine of the

Fig. 13.—Case XIV. S. K., röntgenograph revealing separation of the epiphysis for the anterior superior spine of the ilium.

ilium. While comparatively rare it should be included in this dissertation, as it is the opinion of the author that the condition is more frequent than the literature leads us to believe. When we are trained to be on the look out for this affection, we will find is more often.

Mechanism: most authors agree that the fracture occurs as a result of hyperextension of the trunk on

the thigh. The tensor fasciæ femoris muscle being the strongest of those attached to the anterior superior spine of the ilium, it is the one most active in producing the fracture.

The following case report will help bring out the symptomatology: S. K.; aged fifteen; male; schoolboy; presented himself at the Clinic of the Hospital for the Ruptured and Crippled, May 8, 1924, complaining of pain in the right groin. On May 1st, while running a hundred yard dash, he was seized with a sudden sharp pain in the right groin after traversing one half the distance. This occurred as he raised his thigh and hyperextended the trunk. He stopped running and walked off the field unassisted, suffering excruciating pain; this was somewhat alleviated by having the "leg pulled," as he expressed it. He walked home and remained there until his appearance at the clinic.

Patient walked about without assistance presenting a mild right hip limp without deviation of the body. There were two ecchymotic areas about the right hip, both anterior and posterior to the right anterior superior spine. There was no restriction of motion, although extension and abduction are painful, more especially when lying on the unaffected side. There was a thickening of the parts of the anterior third of the ilium, and immediately distal to it is a small mass, bony in character, about the size of a twenty-five cent piece, tender and adherent to the underlying structures. There was no crepitation nor fluctuation present. Poupart's ligament was not disturbed, although its ilial attachment is tender. Measurements were equal.

Diagnosis of fracture of the anterior superior spine of the ilium confirmed by the x ray.

A low pelvic and hip strapping was applied for two weeks, at the end of which time the patient reported to the clinic, stating that he was entirely well and able to run short distances without discomfort.

CONCLUSIONS

The growing pains of the adolescent may resolve itself into an epiphysitis of the vertebræ; of the diaphyseal portion of the epiphyseal line of the capital epiphysis of the femur; of the tibial tubercle or of the epiphysis of the os calcis.

Traumatism in the preceding plays but a contributory rôle, whereas, in instances of separation of the epiphysis for the lesser femoral trochanter and of the anterior superior ilial spine, traumatism by indirect violence is the sole cause.

A Statistical Study Indicating the Diagnostic Value of Hyperchlorhydria

WILLIAM W. SAGER, M.D.
and HOWARD R. HARTMAN, M.D.
Rochester, Minn.

The present study, the last of a series of three statistical studies dealing with the diagnostic value of various degrees of gastric acidity, is an analysis of 331 cases of hyperchlorhydria in which the acids varied from 40 to 72. More than twelve hundred cases altogether have been analyzed.

TECHNIC

The technic employed was the giving of the usual Ewald testmeal followed in one hour by withdrawal of the stomach contents and the determination of the content of hydrochloric acid both free and combined, expressed in terms of tenth normal sodium hydroxide solution.

Hyperchlorhydria does not necessarily mean the presence of disease, as Bennett, Rehfuss, Bergeim, Hawk, Carlson and others have pointed out. A degree of gastric acidity as high as may occur in patients is found in certain normal persons who are enjoying excellent health. Bennett believes that hyperacidity exists in five per cent. of normal persons, and says that it seems absurd for anyone to claim that hyperchlorhydria alone is either evidence of disease or an explanation of discomfort. Carlson and Rosemann have called attention to the fact that the gastric glands will not secrete acid in greater concentration than from 0.55 to 0.60.

The degrees of acidity in the aspirated gastric juice vary greatly, in this series from 40 to 72, and it is our purpose to determine the percentage of various diseases associated with hyperchlorhydria.

TABULATION

INCIDENCE OF DISEASES ASSOCIATED WITH HYPERCHLORHYDRIA

Disease	*Cases*
Neurosis	96
Peptic ulcer	55
Cholecystitis	33
Indeterminate diagnosis	20
Chronic constipation	17
Chronic appendicitis	10
No disease	10
Carcinoma	9
Syphilis of central nervous system (1 questionable)	9
Pulmonary tuberculosis	4
Psychoneurosis	4
Essential hypertension	3
Multiple polyposis of rectum	3
Renal tuberculosis	3
Tonsillitis	2

Disease	Cases
Angioneurotic edema	2
Chronic mastitis	2
Chronic pancreatitis	2
Hypertrophied prostate	2
Arteriosclerosis	2
Toxic gastritis	2
Ventral hernia	2
Angina pectoris	2
Arthritis	2
Bronchial asthma	2
No diagnosis (examination incomplete)	2
Stricture of urethra	1
Myositis	1
Epigastric hernia	1
Prolapsed uterus	1
Obesity	1
Adenoma of thyroid	1
Hydronephrosis	1
Lipoma	1
Myalgia	1
Hypospadias	1
Pelvic tumor	1
Cirrhosis of liver	1
Prostatic stones	1
Exophthalmic goitre	1
Colloid goitre	1
Bilateral salpingitis	1
Myocardial degeneration	1
Myelocytic leukemia	1
Otitis media	1
Diabetes mellitus	1
Cardiovascular disease	1
Intercostal neuralgia	1
Entamoeba histolytica	1
Adenomyoma of uterus	1
Pyelonephritis	1
Dysmenorrhea	1
Multiple sclerosis	1
Bubonocele	1
Myxedema	1
Secondary anemia	1

In the present series fifty-five peptic ulcers were found, 16.6 per cent. Of this group forty-two were duodenal ulcers, three probably duodenal, eight gastric, and three gastrojejunal ulcers. The gastrojejunal ulcers followed gastroenterostomy performed in three cases for ulcer of the duodenum. There was in this group of cases a decided increase in the percentage of ulcers over that in the group of cases of anacidity studied, and also over that in the group of cases of hypoacidity studied. In the 492 cases of anacidity ulcer was found in only thirteen. Twenty-eight cases of ulcer were found in the group of 420 cases of hypoacidity.

This comparison shows that there is a gradual increase in the incidence of peptic ulcer as the degree of acidity increases.

Thirty-three cases of cholecystitis were found, which shows a decrease in percentage. In the cases of achlorhydria studied the percentage was 18.11 and in the cases of hypoacidity sixteen, whereas in the present series it was a little less than ten. In the second paper, dealing with hypoacidity, the prevailing views relative to the degree of acidity found associated with gallbladder disease was discussed briefly. Gatewood, in reviewing a series of 192 cases of disease of this organ, noted that achlorhydria and hypoacidity were present in forty-five per cent. Griffiths and Simnitsky have stated that hyperacidity and hypersecretion occur in gallbladder disease.

From the foregoing figures it may be concluded that as the free hydrochloric acid of the stomach increases the percentage chance of associated gallbladder disease decreases.

Nine cases of malignant disease were found, only two of which were carcinoma of the stomach and only one of the sigmoid. They included 1, carcinoma of the sigmoid; 2, epithelioma of the lip; 3, carcinoma of the prostate; 4, carcinomatosis of the abdomen; 5, epithelioma of the cheek; 6, carcinoma of the stomach (two cases); 7, epithelioma of the bladder; and 8, carcinoma of the pancreas. The malignant cases were 2.72 per cent. of the total number, a very marked decrease in percentage as compared with the group with anacidity and the group with hypoacidity. In the group with anacidity there was a 20.53 per cent. chance of associated malignant disease, or an 18.11 per cent. chance of carcinoma of the stomach. The chance of malignant disease dropped to 3.1 per cent. in the group with hypoacidity. In the group with hyperchlorhydria the chance of carcinoma of the stomach is less than one per cent., in striking contrast to more than eighteen per cent. in the group with anacidity.

In ninety-six cases (twenty-nine per cent. of the entire group), various functional complaints of the nervous system had been diagnosed. Eighty-seven such cases were found in the 492 cases of anacidity (17.70 per cent.); 158 in the 420 cases of hypoacidity (37.6 per cent.). It is probable that the acids in the latter cases were higher than revealed by the stomach tube, because fear depresses gastric acidity, as has been pointed out by Bennett, Baird, Campbell, Hern, and many other workers.

It is interesting to note the relative incidence of appendicitis, although the number of cases is not sufficient to draw definite conclusions. In the series of 492 cases of anacidity only four with appendicitis were found, in the 420 with hypoacidity eleven, and in this series of 331 there were ten showing a probable increase in the incidence of appendicitis as the gastric acidity is increased. Bonar found achlorhydria and hypoachlorhydria in fifty-five per cent., normal acidity in fifteen per cent., and high acidity in thirty per cent. of cases of chronic appendicular disease without dyspepsia. In such cases with dyspepsia, however, twelve per cent. showed normal acidity and eighty-eight per cent. hyperacidity, with curves of gastric acidity of the duodenal type. As there were also symptoms of dyspepsia in our own cases the results are in accord.

The diseases in the remainder of the cases are so varied that any deduction is impossible and their association with the condition of hyperacidity is probably only a coincidence.

In this series of cases of hyperacidity varying from forty to seventy, peptic ulcer, cholecystitis, carcinoma and appendicular disease were the diseases most commonly associated, their combined incidence being 32.3 per cent.

An interesting review of a large number of gastric analyses was made in this series by Reginald Fitz, but as additional factors are introduced in his work, such as stasis, concentration of acid, and method of expression of results, a comparison of results would require a long discussion.

CONCLUSIONS

From the results of this series of studies, and of this study in particular, it may be concluded that:

1. The degree of gastric acidity is not pathogno-

monic of any disease, although pernicious anemia never occurs in the presence of hydrochloric acid, and gastric syphilis rarely, also, duodenal ulcer is rare in the absence of free hydrochloric acid.

2. The greatest diagnostic value of a knowledge of the degree of acidity lies in the suggestion carried by the large percentage of carcinomas found associated with the condition of anacidity, their rarity with the condition of hypochlorhydria and hyperacidity, and in the progressive increase in the incidence of duodenal and gastric ulcer with the increase of gastric acidity.

Treatment of Constipation*

EDWARD L. KELLOGG, M.D., F.A.C.S.
New York

Hale White, commenting upon the surgical treatment of intestinal stasis, remarked that "surgeons in their reports usually state that medical treatment had been exhausted before resorting to surgery but fail to discuss the methods used. This leads to the suspicion that all surgeons are not familiar with the therapeutic resources available to the internist." The reproach may not be unmerited and has led to the following résumé of the subject:

Constipation is the most common of all ailments affecting people of all ages and in every walk of life. It is particularly the bane of those whose occupation is sedentary. Some persons evacuate their bowels only once in two or three days or less frequently without apparent discomfort, but this sluggish state usually causes disturbance of the health and if the intestinal canal is to retain its healthy state for a lifetime it should evacuate its contents daily.

In old age this is important, for premature senility and many of the infirmities of later life result from the toxemia complicating constipation.

It makes little difference whether the bowels act on arising after breakfast or at night so that the habit is acquired and the fixed time kept. Equally important with regularity is the completeness of the evacuation. Constipation is a symptom rather than a disease caused by several quite dissimilar conditions that must be differentiated in order to apply proper treatment.

Usually there is obvious constipation, the bowels moving less frequently and less freely than normal; or residual constipation, the movement being incomplete even though regular, or more frequent than normal. Diarrhea is often constipation in disguise, the frequent loose movement constituting an attempt to evacuate irritating contents.

*From the Department of Gastroenterology, New York Polyclinic Medical School and Hospital.

DIETETIC

Dietetic constipation is diagnosed by the history and the effect of a properly regulated diet. The food may be lacking in bulk and stimulating properties or is actually constipating comprising such articles as lean meat, milk, cheese, toast and cocoa. It may be due to taking too little fluid or drinking water containing an excess of iron or lime salts. The treatment consists of limiting the ingestion of constipating foods and prescribing those that are laxative. Fruit should be taken freely, particularly oranges, grape fruit, melon, apples, pears, prunes, dates, figs; the mechanically stimulating foods as whole wheat, graham and rye bread, bran preparations as bran bread or biscuit, bran served as a breakfast food alone or mixed with some cereal; green vegetables that leave a large residue, as celery, spinach, green peas, string beans, corn and salad vegetables. The free use of butter, cream, olive oil and bacon tends to soften the feces. A glass of cold water or a cup of coffee on arising will stimulate peristalsis. Water should be used freely throughout the day.

HABIT

Habit constipation results from failure to heed the natural impulse for a movement.

As a result the bowels may become unresponsive so that the rectum holds large masses of impacted feces without stimulating the spinal reflex.

The patient is taught to yield promptly to the desire for a movement and to attempt to have a morning stool. The best time is shortly after breakfast as peristalsis is stimulated by food. When at stool avoid concentrating on the desire for a movement.

Rectal dilators are effective in establishing a regular habit of defecation and can be dispensed with when the habit is established. The largest size that

can be used without pain is lubricated, inserted in the rectum and retained until the desire for a movement is imperative.

SPASTIC

In this condition there is a tonic spasm, usually of the descending colon or rectum. It is often complicated with atony of the cecum and ascending colon. The etiology may be found in some point of local irritation, such as hemorrhoids or fissure, colitis or hyperesthesia. It may be a local manifestation of general nervous tension. Drastic cathartics must be avoided for although temporarily effective, they ultimately increase the irritation. The general suggestions above will be useful but the mechanically irritating foods should be avoided. An increased bulk is desirable, however. Medication will be required and foci of local irritation should be removed. Hemorrhoids or fissures should be relieved by appropriate means. A spasm of the sphincter ani may be overcome by dilation under general anesthesia or more gradually by rectal dilators.

Proctitis or colitis should be treated with bland enemas or ointments or suppositories, i. e., solutions of sodium bicarbonate, bismuth subcarbonate in castor oil, olive oil enemas, suppositories or ointment of oxide of zinc, or orthoform ointment. The application of argyrol solution (twenty-five per cent.) through a proctoscope is soothing and antiseptic. If the area of spasticity is above the rectum the regular use of large enemas is helpful. For this purpose use tap water or solution of sodium bicarbonate or boric acid or a mixture of milk and molasses. In the early stages of treatment an enema of olive oil at bedtime retained during the night and a low pressure enema of sodium bicarbonate solution in the morning is effective.

The usual medication is mineral oil or white petrolatum, atropine and agar agar, or psyllium seed. Mineral oil of heavy density is given freely and if taken at mealtime so that it is intimately mixed with the food, a large dose can usually be tolerated. Occasionally the oil will be discharged involuntarily without producing a movement. When this occurs the dose should be reduced or white vaseline substituted. The dose of the oil is one half to one ounce, of vaseline drams one to ounces one half two or three times daily. The dose of atropine may be small at first (gr. 1-500) increased to the physiological limit if necessary. Agar agar and psyllium seed are best taken mixed with the foods, the dose being one or two heaping tablespoonfuls twice daily. Milk of magnesia may be used as a laxative, particularly if there is also gastric oversecretion as often occurs. The dose may be from one dram to one ounce two or three times daily. If taken about one hour after meals it will not interfere with gastric digestion and will correct acidity.

ATONIC

Atonic constipation may result from general asthenia or follow the excessive use of enemata and cathartics or fermenting food. It is frequently a late development of other forms of constipation. The suggestions made for dietetic and habit constipation apply. The diet should be bulky and stimulating since it is difficult for the relaxed intestine to contract sufficiently on a small bolus and the stimulating effect of the mechanically irritating food is particularly helpful. Some benefit may be derived from mineral oil and rectal dilators. Agar agar alone or containing some simple laxative is indicated. An abdominal supporter helps by increasing the intraabdominal tension. Exercises to strengthen the muscles and compress the abdominal contents are useful. Those usually prescribed are as follows:

One: stand erect, feet close together and without bending the knees try to touch the floor with the hands.

Two: lie on the back on the floor with hands behind the head and without bending the knees or lifting the heels sit up.

Three: lie in the same position and try to touch the floor above the head with the toes.

Each exercise is repeated five or six times morning and night. Abdominal massage self applied may follow the exercise. To do this conveniently a leather covered lead ball weighing six or eight pounds is rolled over the abdomen in the direction of the colon twenty-five to fifty times, with pressure applied particularly over the cecum and ascending colon since this is usually the most difficult part of the colon to empty. The routine use of enemata should be avoided for the weak intestinal wall is easily overdistended and peristalsis becomes more sluggish. They may be required for a time because of toxemia but their disadvantages should be understood. Tonics to restore intestinal tone are indicated, i. e., nux vomica or strychnine, glycerophosphate of lime or soda, hydrastis cundurango, quassia colombo; electricity, abdominal or intracolonic; the Scottish douche morning and night (consisting of alternating hot and cold water sprayed over the abdomen and spine. Small dose of pituitary substance (gr. three) are sometimes extremely effective. A single dose of eserine salicylate is often useful but should be prescribed with judgment as it is a depressant.

MECHANICAL

Mechanical defects may be present from birth even though the bowels move regularly and completely. As degenerative changes develop with age, sedentary habits, or disease, the symptoms may first manifest themselves, although frequently the problem is a life long one. It is often a factor in other forms of constipation and may result from inflammatory conditions. With it we are apt to find residual constipation and autointoxication. A knowledge of the points at which mechanical interference is apt to occur and the usual character of the lesion will be an aid to accurate diagnosis.

Delay at the ileocecal junction will be suggested by gas pains and increased tympany at the left of the cecum. The lesion may consist of dilatation of the ileum, prolapse with angulation or adhesions, appendicitis or an incompetent ileocecal valve which may be demonstrated by repeatedly forcing gas from the ileum into the cecum and back again as shown by the shifting area of tympany after manipulation of the abdomen. The cecum may be dilated, movable or prolapsed, indicated by diminished resistance in the right iliac fossa and increased area of tympany, a palpable cecum which may be felt to move readily under the examining fingers or a splashing sound elicited by vibratory manipulation. Obstruction may occur in the ascending colon (Jackson's membrane) or at the hepatic flexure from adhesions or angulation and is

suggested by a history of gaseous distention proximal to this point, tenderness, discomfort, or actual pain, as the intestinal contents are forced past it, followed by relief of symptoms.

Prolapse of the transverse colon causes angulation at the hepatic and splenic flexures and by becoming adherent may create a point of obstruction. This occurs frequently after pelvic operations, the omentum or the colon itself being held down in the pelvis or becoming attached to the abdominal scar. In this condition pressure upward beneath the transverse colon will occasionally cause pain or soreness or a dragging sensation above the pubes or in the laparatomy scar.

At the splenic flexure and about the sigmoid the same condition and symptoms described at the hepatic flexure may be found. Adhesions may bind the arms of the sigmoid loop together or to the adjacent bowel or it may be abnormally long or prolapsed and atonic or caught in adhesions from pelvic inflammation. Frequently there is discomfort, pain or tenderness in this region with alternating tympany and dullness. The stools may be ribbon like or fragmentary. The sigmoidoscopic examination frequently aids the diagnosis.

In the rectum in addition to the spastic condition described above we may find stricture or inflammation or hemorrhoids, or pressure from without caused by enlarged prostate, uterine pathology, or pelvic inflammation or new growths.

The x ray aids in the diagnosis and to its lessons we are indebted for much of our knowledge. It is always valuable for confirmation and frequently is indispensable. It is a mistake to consider the x ray report as always final, however, for the röntgenologist like the clinician makes mistakes. It is likely to be too convincing and may discourage both patient and physician in their attempt to obtain relief from treatment and may lead to unnecessary surgery. The patient's interest is in normal function rather than perfect mechanics and Nature will often solve the problem if the burden is lightened. Moreover, to operate is not necessarily to cure.

All that has been said above about treatment applies in this condition the difference being that we must recognize in the mechanical changes an incurable condition that always predisposes to trouble. The treatment therefore constitutes a life sentence. When there is a relaxed condition of the abdominal walls and much flesh has been lost an attempt should be made to increase the abdominal adipose tissue by a diet of high caloric value supplemented when necessary with a rest cure. The patient is taught to sleep with the foot of the bed elevated about twelve inches, since in this position some of the mechanical difficulties may be relieved. Assuming this position will frequently cause a loose copious evacuation. Bulky and stimulating foods are indicated but because of the tendency to putrefaction and fermentation—animal proteins are reduced to a minimum and the carbohydrates are carefully selected. The bulky green vegetables and those with a coarse residue are important. Bran is taken freely, often two or three times daily. If the stools are dry, mineral oil is used and agar agar containing cascara or phenolphthalein twice daily. It greatly increases the bulk of the stools.

Laxative drugs will be needed such as cascara or other peristaltic stimulants, also remedies to check putrefaction and fermentation or to aid intestinal digestion such as ichthyol, charcoal, sodium phenolsulphonate, the vegetable ferments, or measures to change the intestinal flora such as introducing by mouth or rectum cultures of bacillus acidophilus or bacillus Bulgaricus. Lactose in considerable quantity is a remedy of value and brewers' yeast acts well in some cases.

Residual constipation is apt to be present and will be indicated by offensive stools, intestinal fermentation, coated tongue and indicanuria. To avoid this, it is well to establish a regular castor oil habit. Once every week or two a purgative dose of oil is taken. An occasional mercurial will be helpful by promoting the flow of bile which is likely to be diminished.

Senna, although a mild laxative, is often quite effective in the form of pulv. glycyrrhiza co. or senna prunes. Support of the abdomen is indicated. It should be applied with the maximum pressure above the pubes and iliac crests. The type of supporter chosen will depend upon the shape of the abdomen. The pendulous or prominent abdomen may be supported by an elastic belt but the flat or retracted abdomen will require a special supporter, either that of Curtis Lane or a supporting corset. For temporary use the adhesive plaster belt of Achiles Rose is very effective. We must not lose sight of the fact that if the cecum is prolapsed into the pelvis a belt may do harm by compressing it at the pelvic brim. Abdominal massage and exercises and rectal dilators will be useful.

Enemas may be required. For this purpose the long rectal tube may be dispensed with except in the occasional case in which it is introduced directly into the sigmoid through a proctoscope. The short rectal tube and the knee chest position are desirable, the column of fluid being sufficient to fill the colon. Transduodenal lavage (Jutte) is helpful in the early stages of treatment as it stimulates peristalsis and diminishes toxemia.

In most cases of constipation in the beginning it is advantageous to use several methods of controlling the condition, discontinuing one after another the unnecessary and more troublesome procedures.

In the minds of the laity, the reaction against the injurious effects of strong purgatives and the propaganda in favor of socalled physiological methods has led to a morbid dread of laxative medication which is hard to overcome.

While it is desirable and usually possible to develop normal evacuation by means of diet and exercise in young people, these methods are likely to be only partially successful in those past middle age. Patients should be taught that the evil effects produced by prolonged absorption of intestinal toxines are far greater than those which result from the use of vegetable laxatives. If all the methods fail or they become so burdensome as to interfere with the comfort and efficiency of the patient, surgical treatment may properly be considered.

The procedure will vary since it is a question of the best and least hazardous means of overcoming a mechanical difficulty. Shortening the gastrohepatic omentum, which by lifting the stomach may also draw up the transverse colon; a plastic operation on the ileum to free it from adhesions and anchor it in a favorable position; repair of the incompetent ileo-

cecal valve; appendectomy; removal of constricting bands in Jackson's membrane; plication of cecum and ascending colon; suturing a prolapsed or movable cecum to the posterior abdominal wall; restoration of the hepatic flexure or division of adhesions in this area; resection of cecum and ascending colon; some procedure to support the transverse colon; lowering the splenic flexure or dividing adhesions at this point; dividing adhesions of the sigmoid, sigmoidopexy, resection of sigmoid, ileosigmoidostomy with or without colectomy (rarely indicated); various operations upon the rectum such as stretching the sphincter ani, removing hemorrhoids, dilating strictures; operations upon other organs for the relief of pressure.

THERAPEUTIC SUGGESTIONS

A cup of black coffee or a glass of cold water on arising are good peristaltic stimulants. The free use of water throughout the day tends to soften the stools.

Tobacco is a laxative for many people.

Fruit is more effective alone than when taken with other food. The laxative effect depends upon the bulk of the residue, mechanical stimulation and the laxative salts they contain.

Green vegetables also act by their bulk and mechanical stimulation. They are not so uniformly rich in laxative salts as the fruit (exceptions are tomatoes, rhubarb).

Bran is a good mechanical stimulant. It may be taken as a cereal or in the form of bran meal or muffin or Scotch scone.

The importance of minute subdivision of active substances was known even to the ancients. A smaller quantity of the active substance is sufficient and it is less likely to do harm. The action is more moderate and equable if mixed with an inert substance.

Scamony is useful as a single dose to expel hardened feces. It is an active and searching purgative but it is too irritating for continual use. It is best combined with other drugs.

Jalap is a hydragogue cathartic and is a useful laxative when it is desired to remove dropsical effusions.

Senna (leaves) makes an excellent and safe cathartic, but is likely to cause griping and for that reason is usually given in combination with other drugs. Its laxative properties are derived from salts of cathartic acid.

There are a number of well recognized formulas. The compound liquorice powder has been a favorite preparation for years. The confection of senna is well taken by children.

Aloes (socotrina) is useful in atonic constipation as it stimulates the muscle coat as well as the mucous membrane. Aloin is about three times stronger than aloes and the dose must be calculated accordingly.

Continued use may cause irritation of the colon or rectum. It is best mixed with other less active substances.

Decoction of aloes has an agreeable bitter taste. It was formerly a famous recipe and enters into the composition of valuable drafts prescribed in former times.

Podophyllin is useful in chronic constipation when it is desired to stimulate the liver. It is perfectly suited to some people while in others its effect is uncertain or may cause severe griping.

Elaterium is a drastic purgative. Its use is limited but it may be used in cases in which it is desirable to relieve congestion of the brain or in dropsy.

Croton oil is a drastic cathartic and dangerous if not used carefully. Its particular field of usefulness is in cases that are unconscious as apoplexy. Two drops may be used with enough alcohol to dissolve it and may be given on a piece of bread or dropped on the tongue.

Rhubarb is an excellent purgative. It has been claimed that the aftereffect is constipating but this has not proved a practical objection in my experience. The Turkish rhubarb may be obtained ground and compressed into cakes (rhubarb fingers).

Many patients regulate their bowels by chewing a small portion several times daily, quickly learning their individual dose.

Mixed with bicarbonate of soda it is a useful laxative in digestive derangements.

SALINE LAXATIVES

Most salines act partly as purgatives and partly as diuretics. Some of them act not only by producing osmosis of fluid from the blood because of their higher specific gravity and influence on nerve findings in the mucous membrane, but also in consequence of their being absorbed into the blood and then excreted into the intestines. Salines are more powerful combined than separately and their effect is expedited and increased if taken in warm water.

One of the best is magnesium sulphate. If taken dissolved in warm water, it is more promptly effective, combining nitre with it makes it an excellent diuretic also.

Carbonate of magnesia is very mildly laxative producing a soft movement without irritation. Because of its antacid properties it is an excellent laxative when we are dealing with hyperacidity also or in spastic constipation. It is valuable in infancy and childhood and is effective for many adults.

Sulphate of soda or Glauber salts is milder and less disagreeable than epsom salts.

Phosphate of soda is a mild purgative for both children and adults. It may be given advantageously in broth or soup and may be continued for a long period without unpleasant results. Its continued use seems to have an inhibitory effect in chronic rheumatism.

Rochelle salt is laxative and diuretic. The organic acid in this salt like citric acid becomes changed in the system to an alkaline carbonate making the urine alkaline.

Seidlitz powder is a refreshing effervescing saline laxative.

The numerous laxative mineral waters are—most of them—effective in proportion to their percentage of sodium or magnesium sulphate.

Cascara sagrada is useful in the treatment of chronic constipation. It acts as a stimulant to the muscle coat, but may irritate the mucous membrane.

Castor oil is an excellent purgative and is valuable in combatting toxemia. It is thorough and has a soothing effect on the mucous membrane but the after effect is constipating, and this must sometimes be corrected by giving a saline laxative on the succeeding day. It is effective as an enema and is suited to all ages. There are many remedies for covering the objectionable taste—coffee, fruit juices, whiskey, fluid extract sarsaparilla, or liquorice, etc.

As good a method as any is to rinse a glass in ice water, put an ounce of ice water in the glass, float the oil on it with a layer of water above and take it at a single gulp. Another method which is a favorite in some hospitals, is to put in the bottom of the glass the juice of an orange, above this the oil, and add a teaspoonful of soda bicarb. Stir and drink while effervescing.

DUODENAL IRRIGATION

This is a valuable method of treatment when the patients are toxic. It is usually given once a week or more frequently in suitable cases. The method has been described by Jutte. The tube is passed into the duodenum and the medicated solution is introduced through it producing a prompt and thorough cleansing effect upon the entire intestinal tract.

TAMPONS

By using a sigmoidoscope the sigmoid may be directly medicated by tampons saturated with appropriate remedies. This is useful when dealing with a local or limited lesion. Suppositories offer an easy means of medicating the rectum and are efficient in suitable cases.

Ointments have a limited field of usefulness in the treatment of constipation. In lesions of the ano rectal margin such as fissure and hemorrhoids they are of considerable help.

Vibration and electricity applied abdominally or with one electrode in the rectum are useful adjuncts to other treatment.

Enemas may be given for their stimulating effect, to relieve spasticity by their soothing effect, or by neutralizing organic acids, or to introduce helpful bacterial cultures into the colon. The long rectal tube may be dispensed with since it is mechanically irritating and not necessary. The knee chest position is best but lying on the back or left side with the hips elevated is sufficient. Occasionally it will be found desirable to introduce a long rectal tube directly into the sigmoid through a proctoscope.

If an enema is warm, introduced slowly and with little pressure it is possible to give it thoroughly with very little discomfort particularly if it is interrupted at first to allow the expulsion of gas. The same rule applies in administering irrigations. With care in regulating the temperature, the pressure and flow of the solution, permitting the expulsion of gas and fluid at the first suggestion of pain, and then continuing the introduction of the fluid, it is possible to thoroughly irrigate even a very sensitive or irritable colon. The y tube, a straight rectal tube, a container for holding a sufficient quantity of fluid, the various connections and receptables for catching the fluid comprise the only necessary equipment.

CONCLUSIONS

Constipation may be grouped under the headings: dietetic, habit, spastic, atonic and mechanical constipation.

Treatment may include diet, exercise, massage, electricity, abdominal support and indicated drugs. Most cases can be best treated by using a combination of several methods. Mechanical constipation does not necessarily require operation. The x ray examination should be accepted as only part of the evidence and should not discourage attempts to cure by treatment.

Operation should be considered only after the failure of other methods.

Note on Hypoglycemic Reactions During Insulin Treatment

With Report of a Case

A. V. GREAVES, M.B. (Tor.)

Nassau, Bahamas

Our knowledge of the exact mode of action of insulin upon the human organism, together with the details of intermediate carbohydrate metabolism, are not so well known that we can afford to neglect the evidence that clinical observation of cases under close control may offer us, and it will be largely by the accumulated clinical experiences of many different observers that our knowledge of the best practical application of this potent extract to the alleviation of diabetes mellitus will be arrived at.

The somewhat unusual features of the case detailed in this communication seem worthy of record.

Case.—The patient, C. S., a man forty-five years of age, gave a history of having been under a physician's care in 1921 for diabetes and having followed a modified diet in the interval with some amelioration of symptoms until January, 1923. At this time his thirst, polyuria and other symptoms became again noticeable and he was referred to another physician for treatment.

After preliminary strict dieting he was placed upon small doses of insulin (which was then available in small quantities in Toronto) and apparently improved markedly in a clinical way, although still showing occasional slight glycosuria. He was taught to select, calculate the value of and weigh his diet daily and passed out of control on a diet containing carbohydrates 78, protein 100, fat 180, with fifteen units of insulin twice daily. From this time (October, 1923) until the date of his coming under my care (December, 1924) he said he felt and looked so well that he became careless and ceased weighing his diet and testing his urine as he had been taught to do.

On December 26th I was called to see him and found him in a state bordering closely on coma. His breath was heavy with acetone, his respiration of the Kussmaul type and he was drowsy but could be roused sufficiently to answer questions in thick, slurred accents. His lips were dry and cracked and his tongue a beefy red. He showed definite edema

of the face and pitting could be demonstrated over both tibiæ. The temperature at this time was normal, but his pulse was 110.

ANTECEDENT HISTORY

His immediately antecedent history was difficult to obtain, but as far as I could gather he had not been quite well for about six days, having had a head cold; but for the three days previous to being seen he had vomited frequently and had kept practically nothing down. He had taken no insulin since beginning to vomit. He complained of no headache, but his vision was so blurred that he could see little more than outlines. A blood sugar estimate showed 0.51 g. per 100 c.c. and his urinary sample contained five per cent. sugar and gave a strongly positive test for ketone bodies and a marked reaction for albumin. Microscopically there were a few white blood cells and many granular casts.

TREATMENT

He was given forty units insulin immediately by hypodermic injection and removed to hospital, where he received five hundred c.c. ten per cent. glucose with forty units insulin by vein. On the same evening he was given a further five hundred c.c. glucose by Murphy drip and thirty units of insulin. On the following day he only vomited once and was markedly improved clinically. From this time he was fed by mouth. His fasting blood sugar was 0.47 per cent.

He was sufficiently well on January 3rd to return home with a nurse and at this time was receiving three doses of insulin daily before meals, totalling 140 units with an intake of carbohydrates 50, protein 45, fats 45. His twenty-four hour urinary sample showed two per cent. sugar and a marked ketone reaction. The fasting blood sugar was 0.30 per cent., but examinations made at various times in the afternoon of the two days preceding showed as low as 0.09 per cent. sugar. The urinary albumin and casts had completely cleared up. The slight edema noted at first was still present and remained for six weeks after the onset of the illness.

HYPOGLYCEMIA SYMPTOMS

It might be well to note here that this patient was thoroughly familiar with the symptoms of hypoglycemia, having experienced mild reactions frequently when first being placed on insulin treatment; he was moreover warned at this time to be on the watch for symptoms of reaction and a glass of orange juice and glucose was at all times beside his bed so that he could apply the appropriate treatment without a moment's delay by merely stretching out his hand for the glass. Such precautions were considered advisable owing to the high insulin doses employed.

On January 6th his urine showed three per cent. sugar during the after breakfast period but was free for the rest of the day. A blood sugar was arranged for the following day but unfortunately could not be carried out.

On January 7th his urine was sugar free for the whole day except for a trace one hour after luncheon.

At 9 p. m. on this day, three hours after patient's evening meal with forty units of insulin, I was called urgently to see him as he was thought to have fainted. I found him quite unconscious in a hypoglemic state. As he was quite unable to swallow I injected ten min. 1-1000 adrenaline chloride hypodermically; this caused the swallowing reflex to return in about three minutes. Glucose was then fed to him until he returned to consciousness, which was complete about five minutes after he commenced to swallow.

THE ATTACK

The history of the attack was as follows: his sister was in the room with him when he asked casually for a drink of water; she poured it out immediately but on turning to hand it to him found him practically unconscious and unable to swallow.

He stated to me afterwards that he had not the slightest recollection of the occurrence. There can be no question of the overwhelming suddenness of the onset of the symptoms and the patient's genuine surprise when he became aware of the nature of his attack.

RÉSUMÉ

On thinking over the case in an effort to account for the sudden lowering of the blood sugar (after a glycosuria on the previous day) I recalled the fact that ever since coming under my observation he had shown a persistently rapid pulse although his temperature was never over 100. I had been unable to account for this and the point only obtruded itself after the occurrence detailed above. The whole picture I believe to be explained by supposing the initial coma to have been due to the supervention of an infection (an acute cold or influenza) in addition to careless dieting, with a consequent marked loss of carbohydrate tolerance; the later state of hypoglycemia being due to the sudden development of immunity to the infection (the ordinary process of recovery) with the equally sudden regaining of a high level of tolerance. Both the normal temperature and the high pulse rate in this case was later made clear to me by Campbell's observation that in marked diabetes with high blood sugar levels the elevation of temperature normal to an infection is frequently absent and in this way the presence of such an infection may escape detection; the pulse, however, does show the proper increase commensurate with the severity of the infection.

The lesson to be learned from a case such as this is that in grave diabetic crises the frequency of the pulse rather than the degree of temperature should be taken as the guiding sign pointing to the presence of an infection; also that increased carbohydrate tolerance may follow closely upon the subsidence of infection, even to the point of suddenness, and for this reason close attention should be paid to such patients if on high insulin dosage in view of possible sudden hypoglycemia consequent on the subsidence of an infective process.

It may be of interest to mention that this patient's pulse returned to normal a few hours after the occurrence of the hypoglycemia.

The Use of Sedatives, Tonics, Endocrines, Etc., in the Reeducational Training Treatment of the Epileptic

L. PIERCE CLARK, M.D.

New York

(*Concluded from page* 156)

I have so thoroughly detailed these principles in other papers that I need not reiterate them. Suffice to say that when a proper setting for the individual patient is supplied and all his natural demands and interests are adjusted, he has his best chance to recover.

Before we leave the subject of sedatives in treating the epileptic seizure epoch, it may not be out of place to note other uses for them; that is, their value in differential diagnosis, in separating the epilepsies from hysteria, and their use in indicating the degree and kind of epilepsy in the particular case. It is fairly well known that sedatives are of little or no use in repressing hysterical convulsions, and they have no enduring value in warding off epileptiform attacks in organic or symptomatic states which simulate essential epilepsy. Chloral is of much more value than the bromides in this latter respect, and in my experience the administration of luminal is even better than chloral in organic epilepsy. In a given case of essential epilepsy it is often desirable to measure experimentally the severity of seizure outlet which the individual finds essential, as it were, to square himself with his disordered wellbeing, for many epileptics seem to require a rhythmic seizure frequency, and by carefully graduating the dosage one may determine how much sedation the individual case may require to materially dislodge the periodicity of attacks and extend the free interval. If the seizure frequency of a certain epileptic requires a high dose of sedatives, say ninety to one hundred grains, we may then conclude that he is severely epileptic. Nor is the advantage of the use of bromides confined to such instances. Often in severe grand mal, by purely repressing the attacks one may so slow down the convulsive discharge as to recover the initial departure of the discharging area in the motor cortex; in many instances where the aura once present was later lost or swallowed up in the rapid advance of the seizure, this phenomenon can be recovered by the process of gradual repression of the onset of the seizure. Again, the maximum advantage, perhaps, is to be gained in the partial suppression of the attacks as a whole and to note the content of the mental state or behavior disorder induced by the sedatives (2).

When we return to the reverse aspect of drug medication in epileptics we pass naturally from a negative to a positive phase of treatment. We realize that there are few drugs that signally help us, as our main dependence is placed upon natural remedies to increase the health of the whole organism. In other words, we not only abandon sedatives for the seizure epoch but we also repudiate the entire principle of the previously assumed nature of the malady itself—that it is a disorder in which the seizures are the sole or main symptoms.

In theory and to a certain extent probably in actual practice, certain epileptics ought to benefit and perhaps have benefited by the use of ordinary *tonics, alteratives,* and other *reconstructive medicaments.* Physical therapy in its various forms is eulogized and there seems to be no reason why drugs should not have a place. Thus we should expect to find mention of iron, codliver oil, arsenic, strychnine, phosphorus in various forms, and so on. But in the literature of epilepsy such drugs are mentioned only in the most meagre fashion. In the collections of drugs found in the exhaustive reference works of leading epileptologists they are almost ignored and in the treatment recommended by the scores of writers of textbooks on neurology and in special journal articles the same silence prevails. Arsenic is usually mentioned only as an antidote to bromides. A few have recommended strychnine in tonic or increasing doses apparently for the neurasthenic component in epileptics. Occasionally there may be mention of glycerophosphate of lime. Such drugs are mentioned only in the most casual fashion. If iron were given there would be evidence of some form of anemia and the drug would be used with reference to improving the blood counts. If strychnine or arsenic were given there would be cases showing the mode of increasing the dose, the symptoms indicating approach to the limits of tolerance, the gain in weight or other check on the salutary action. Unfortunately, then, many of these have been given no adequate trial as they are only too frequently employed to ward off the evils of a bromide sedation. Thus handicapped, they have nevertheless shown themselves to possess no little virtue to assist in improving the functions or structure of the epileptic economy. If they are combined with stimulation therapy, such as special gymnastics, hydrotherapy and proper foods, their efficacy may be signally increased. Nor should the temporary increase of frequent seizures deter one from advancing such a drug therapy, especially when colligated with other principles of physiotherapy. In fact any well authenticated drug that will materially increase the physiologic effectiveness of the epileptic economy should not be despised. Had as much experience and stress been placed upon this aspect of the medication therapy of epileptics as upon the less constructive bromide sedation, we should not have found ourselves so defenseless in meeting the present situation of drug administration. In this same category one may mention the long series of interrelated mishaps that so naturally result in the epileptic's weak economy. Often the irregularities of digestion are not primary but rather are due to the neglect of a naturally weak function and the consequent inroad of noxious bacteria; the remedies in this special category are legion and are usually combined with physiotherapy. A few may be cited. Their employment in the epileptic economy is not essentially different from

their use in nonepileptics, and the reader may refer to special works on this subject in general. Here, again, theory and practice are at fault, however. We find little concerning the state of the stomach in the epileptic. The absence of normal acidity is believed to be one of the factors which favor intestinal putrefaction and which render it unwise to give putrescible animal protein, but we find few analyses of stomach contents involving large hospital material. Strychnia is sometimes found mentioned as a tonic for hypomotility of the stomach. The chief dietetic resource in epilepsy being the salt free regimen, this when employed automatically excludes other measures. This is also true of the vegetarian and milk diets sometimes used. When the epileptic is on a strict diet of any sort the need of medication recedes. One reason for the inutility of stomachics for many epileptics is the common habit of bolting the food and of rapid eating in general. Unless this habit can be corrected in some fashion it could avail little to prescribe medicines. Another and still stronger one is the action of the bromine on the stomach, this element tending to replace the chlorine of the hydrochloric acid. It is known that when large amounts of bromine are ingested daily the elimination of chlorine from the body is so extensive that the stomach secretes hydromic acid instead of hydrochloric acid. It would appear that under the use of luminal and perhaps some other anticonvulsive remedies in use when given to replace the bromides the stomach chemistry would be much less interfered with so that drugs might be exhibited with profit for the improvement of the gastric functions. The custom of giving small doses of bromides in various dyspepsias with a neurotic element is of course unavailable in an epileptic under bromide medication.

The success of such medicaments in the hands of skilled physicians accounts in no small degree for many epileptics being found in the hands of such specialists rather than epileptologists. Excluding the food faddists, an equal number may be found rightly in the hands of practical dietitians. Unfortunately the one sidedness of such otherwise excellent therapy fails of its final goal. It is thus found that even a weak system of special drug therapy in which the totality of the epileptic economy is given consideration, there is much to be gained.

Endocrine therapy.—While much under this head is both vague and fanciful it is certainly indicated in any epileptic with noticeable evidences of endocrine disorder to administer one or more of the following thyroid, ovarian and pituitary preparations. Apparently adrenalin is contraindicated in all cases and the others may be dismissed as inert or doubtful despite theoretical indications based on physiology. In certain conditions of endocrine nature in epileptics in which there is an excess of some secretion there would also be a contraindication. Thus in all disturbances which point to the hypophysis an x ray of the base of the skull should be taken and if there be an acromegalic component pituitary extract should of course be withheld. In such cases, moreover, it is a question whether the epilepsy be not due to the increased intracranial tension which proceeds from the presence of the enlarged hypophysis. This would not strictly speaking be an endocrine case at all but would be symptomatic epilepsy from cerebral tumor. The state of the sella seems to furnish the clearest indication for any endocrine preparation and when found to be small, pituitary extract should be given with thyroid, the latter being usually added to the other endocrines, as pituitary and ovarian substances. Thyroid and ovary may be used when they seem indicated unless some contraindication is present.

In regard to suprarenal extract, it is claimed that adrenalin can induce convulsions in an epileptic (3). Convulsions appear out of the regular schedule in from one half to two hours in about two thirds of all tested. The surgical reduction or unilateral extirpation of the suprarenal glands has been practised extensively for the past few years in extremely severe cases as a last resort to arrest the convulsions. The intervention is formidable and after brief successes the cases have a tendency to relapse.

There are considerable variations of the bony formation of the sella turcica in epileptics (4). Comparative studies of this region in health and disease are still to be made. We are soon to face, however, the problem more definitely and solve its bearings on epileptic states. The issue will be, not so much upon the significance of the relationship which sella deformities may have to the cerebral content itself, as the bearing the variation has upon the possible alteration of function of the posterior lobes of the pituitary bodies, and the rôle this defect or alteration of function may have upon convulsive disorders of epileptics in particular. Posterior lobe extracts have been long since used in the therapeutics of epilepsy independent of any special indication other than the strong feeling that some deficiency of the ductless glands lay at the foundation of the disease.

All *physical practices,* such as compression of a limb, slapping or blistering the extremity to which the aura is referred, etc., have little or no use in preventing an epileptic attack. There is practically no effective treatment of the attack when once it is initiated. At the onset of the paroxysm one may prevent tonguebiting by placing some article—usually a handkerchief or some part of the patient's clothing—between the teeth. The patient's collar should also be loosened. The presence of someone sleeping in the same room may prevent strangulation in nocturnal attacks by the patient lying on his face.

Electricity.—Direct applications of the electric current may indirectly benefit epilepsy in a very small number of cases by benefiting the patient's general condition.

Hydrotherapy.—In selected cases hydrotherapy is beneficial to epileptic patients. It often does good by relieving the effects of bromide intoxication. It can only benefit the epilepsy through the favorable modification it induces in the patient's general condition. The methodical tests made by Fleury confirmed this fact.

Influence of concurrent diseases.—De Montyel and Dide thoroughly investigated the relationship between malarial infection and epilepsy in severe cases. While they do not deny an apparent improvement under such an infection in some cases they cite fourteen instances followed by grave results. In no instance were they able to say that the epileptic attacks disappeared with the appearance of malarial faver. These writers agree with Féré that the chances for

improvement are too uncertain to warrant the utilization of bacterial products in the practical therapeutics of epilepsy.

The author with Dr. A. E. Sharp studied five cases of measles and seven of erysipelas occurring in epileptics at Craig Colony. The result of our study showed that in not one instance was the preexisting epilepsy favorably modified for any great length of time.

Antiautointoxication treatment.—Much has been written on the socalled antiautointoxicants in epileptics. In spite of the fact that one theory after another has been exploded, the belief that there is something radically wrong in the epileptic soma persists, and the clinical sense of the rightness of this surmise will not down. Is the epileptic fundamentally incapable of final combination of food stuffs and does his metabolism seriously suffer as a primary fault; or is it due to his physical handicaps induced by his advancing disease? We do not know; only time and further studies in this field will clear this point. A few would seem to be worthy of empiric trial if upon no other grounds.

Study of authorities appears to reveal that only certain types of epilepsy are accompanied by and perhaps determined by an autotoxic state of the stomach and intestines. This type is recognized by Voisin and others. Akin to it is the type of the disease in which attacks of overeating or improper eating seem to be required to elicit convulsions. The bulimic epileptic who habitually bolts his food may be another in which there is a bond between the state of the gastric functions and the expression of the disease. But aside from these types it does not appear that epilepsy is a matter of gastroenteric autointoxication and the theory and practice of Reed and his followers in finding intestinal stasis as the essential factor in epilepsy is not scientific. A gastroenterologist (Bastedo) states that there are but three things to do in connection with the gastroenteric functions of the epileptic in general. First limit the intake of animal or vegetable food which is putrescible including meats, eggs and legumes. Raw eggs are thought to be especially bad. Second, empty the colon but only by the use of laxatives, cathartics being contraindicated because they so accelerate peristalsis that the albumin has no opportunity for normal digestion and the more readily putrefies. Third, the liver should be stimulated in its various depurative functions although no technic is given to produce this result.

There have been several radical plans of treatment based on the principle of antagonizing autointoxication, such as starvation and the surgical treatment of intestinal stasis including resection of the bowel. In its mildest form, bearing in mind the gluttonous tendencies of many epileptics, this idea is carried out by restricting the diet to easily digestible food, cutting out meats and alcohol and in general by a course of personal hygiene of the digestive organs. Sometimes a more strict vegetarian regimen has been tested, and the salt free and salt poor diets, in addition to making possible reduction of the dose of bromides, may be visualized as well calculated to antagonize intestinal autointoxication.

It is claimed that actual *starvation treatment* has been tested in institutions at various times and that Guelpa, the originator of the starvation cure of diabetes, tested the same principle on epileptics but without sufficient success to warrant an extended report of the experience. Recently an osteopathic practitioner obtained some prominence by favorable reports which attracted much attention in lay circles. Several neurologists in the United States and Canada repeated the experiment and while the immediate results were in some cases strikingly favorable, the seizures returned so soon as the patient went back to eating a normal amount of food. It is at present uncertain whether or not occasional periods of fasting will be able to modify the course of the disease.

Low protein diet.—The views of neurologists on the ill influence of a high protein diet in epilepsy show great variation. Some would apply the low protein diet only in a certain group of epileptics with evidences of intestinal autointoxication, while others would subject all epileptics to it to be on the safe side. We find the statement without reference that at one of its sessions the Psychological Association of great Britain and Ireland made the meat diet in epilepsy a subject for open discussion and that the consensus of opinion was in favor of a meat poor diet. On the other hand extensive researches by Cuneo, an Italian laboratory investigator over many years of the metabolism of epilepsy, dieted one series of epileptics with a regimen consisting almost wholly of meat while another series received a meat poor diet. Contrary to all expectations the high protein diet seems to have reduced the number of convulsions while the carbohydrate diet had the opposite effect. It seems that the latter favors the development of an acidosis which in its fluctuations has an intimate connection with the development of critical and periodical manifestations. He therefore recommends both the cutting down of carbohydrates in the diet and the administration of alkalies. It does not, however, appear that he recommends the high protein diet which would doubtless in any case be expensive even if harmless.

Opium-bromide treatment.—My first illuminating experience was with Flechsig's opium bromide cure. It will be remembered that this system had many strong adherents both in this country and abroad, due, perhaps, to its inception by one of the then prominent neurologists at Leipzig. In many instances the defunct methods of curing epilepsy have had similar origins, such as the Brown-Sequard remedy which in its day was supposed to be a sure cure.

Opium was recommended in epilepsy by Paracelsus in the fifteenth century. Opium alone is seldom used in epilepsy. While its power to suppress the attacks temporarily may not be questioned, its danger in other respects is great. Flechsig (1893) originated a method of employing opium and bromide in conjunction in epilepsy. He recommended this treatment only in chronic cases in which the bromides alone had failed, and cautioned that the patient be carefully watched during the whole course of treatment. The treatment has been extensively used in Germany in cases in which the ordinary bromide and other forms of medicine have proved unsatisfactory, which means that a large proportion of such cases are eminently chronic and refractory. It is selfevident that so heroic a plan of treatment would not be undertaken unless there was urgent need of it and unless a certain percentage of the patients can improve under it.

The patient is virtually turned into an opium eater and then, while still suffering from abstinence symptoms, is poisoned by massive doses of bromide; after which he goes under an ordinary conservative bromide cure, like the majority of his fellows. The patient is under the influence of opium for six weeks or more and the dose is progressively increased until he is taking in the neighborhood of one gram daily, when it is suddenly discontinued. Numerous patients do not suffer during this part of the cure and readily adapt themselves to the increasing doses, but others, as the drug is pushed, show numerous by-effects and it is the custom to keep the ordinary patient in bed on a soft or fluid diet and to give him constant care along the lines of personal hygiene including daily bathing.

In regard to the rationale of the treatment, opium is an ancient antiepileptic remedy which was driven out, prematurely perhaps, when the bromides were introduced. Moreover, opium is a valued remedy in all of the depressive psychoses and hence the treatment is thought to be indicated especially in epileptics with depressed psyche. Over this component the drug seems to exert a beneficial action, while the bromides themselves tend to increase the depression and maintain it. It is known to psychiatrists that morphine alone cannot replace opium in this connection, the improvement in the mental state being due to the association of morphine with some of the other alkaloids of the drug. While an accurate dose of opium is maintained throughout, the state of the pupil is the true means of control; for the drug must not be pushed to the point of the pupils becoming too contracted and insensible. At the sudden suppression of the opium with the patient doomed to some days of withdrawal symptoms, bromides are substituted in daily doses of ninety to 135 grains, with the result that bromism is very apt to develop. According to Binswanger it is at times almost impossible to distinguish whether the distressing symptoms of this period are due to the withdrawal of the opium or the overaction of the bromides. However, the latter drug, with the soil prepared by the opium cure, exerts a profound action on the nerve centres, and in a week the patient, who has now recovered fully from the opium withdrawal, begins to feel greatly improved. The large doses of bromides are now replaced by relatively small ones and upon these the patient remains indefinitely. The attacks in favorable cases have been reduced notably in number and severity and the mental state is much benefited. A second Flechsig cure may be undertaken at any time although this course is not usually followed.

Not all of the patients thus treated are of the type just outlined. Some of them are vigorous and have relatively few seizures. This type of patient resists the opium and it may not be necessary for him to go to bed during the treatment. Not a few children, some of them extremely young, have received the treatment despite the fact that children are intolerant to opium. The dosage is, of course, much smaller and to offset the small doses the child is kept under the influence of the drug for a much longer period than the adult.

The verdict of those who have tried the method is almost uniformly unfavorable, including Donath, Dohme, Landois, Luske, Kathe, Homen, Liehen, Warda, and Bratz, as well as my own experience. Bratz in the treatment of forty-six cases met with three cases of status epilepticus and several cases of severe mental depression (Gowers). Some writers report more favorably and uphold the statement that the treatment of Flechsig is of value for many patients, especially in old and obstinate cases when all other agents have proved ineffectual (Church and Peterson).

In this connection the occasional effects of morphia in epilepsy should be mentioned. Bad effects are apt to follow when the period of epileptic coma happens to coincide with the sleep induced by the morphine. Gowers mentions a case in which an epileptic about to undergo a surgical operation was given ¼ grain morphine to relieve great pain. As the drug was beginning to take effect, the patient had a seizure and immediately passed into profound coma that rendered artificial respiration necessary for an hour.

Chloretone.—The results of chloretone are not unlike those of Flechsig's treatment. When pushed to as high dosage as seemed safe it lessened frequency and severity of attacks. Coincidentally it caused marked somnolence, headache and vertigo. In most cases six grains three times a day is sufficient.

Crotalin is stigmatized as dangerous by the American Medical Association while the daily press has been much used in its publicity campaign. Numerous epileptologists have tested the remedy and statements are common that the strong claims of the venders are not sustained in any respect.

Brown-Sequard treatment.—This consists in giving small doses of mixed bromides combined with iodides for a period of two years without any attempt to increase the amounts of drug during this period. The bromides used comprise the potassium, sodium and ammonium salts with the iodide of sodium and ammonium. At the same time the patient receives a tonic of strychnia and dilute sulphuric acid after meals. The daily use of bromides was a little over one dram, one half of which was taken at bedtime and the other half divided before each meal. Despite the small and nonincreasing dose, good results were reported at the end of the period. The object of the small dose was to prevent the evil of bromism. The treatment possesses only historical interest, although the custom of giving mixed bromides is still in general use. The plan was of course well suited to the exigencies of private practice when the disease could be managed in the patient's home.

PRINCIPLES

From all the foregoing, what are the outstanding principles which underlie the physical treatment of the epileptic? First the attempt to treat the disease process itself based upon some suppositious theory of its causation, visceral, endocrinic or metabolic and the like. Inasmuch as these theories of causation rest upon the slenderest foundations they ought by and large to disappear from daily or even occasional use as they are doing, but unhappily for the welfare of many an epileptic, not sufficiently rapidly. The great majority of the remedies rest upon a more secure rationale if not upon a more successful one, that is upon the basis of suppression or sedation of the disease process as expressed in the fit and its cogeners. Supposing for the sake of argument one postulates the most highly prized physical concept of

the disease, that it is a cerebral affection cortical in origin and that the actual tissue lesion is a form of marginal gliosis either primary or secondary, and that the fits are in some way a periodical expression of this enduring process in the cortex; what use can the sedatives be in such a problem? No one pretends to say that bromides can favorably influence a cortical gliosis. That would be quite absurd. When, then, should this remedy be given? Simply because we are groping in the dark and have found a temporary means of magically suppressing the periodic fits, we imagine we have rid the patient of the disease process. In following this fallacious empiricism we are but practising a false procedure and are really entitled to little more respect than the patent-medicine vender. Again, we are not alone in this odious burden, for the relatives and the patient himself demand we shall above all suppress the periodic occurrence of attacks. If we shall not allow ourselves to be stampeded into a course of inquiry and therapy that is a glaring shame to all concerned, then we must go deeper and build better in a knowledge of the cause and remedy of the individual case. While we may not clearly say that bromides increase the disease, we do know that so far as we can comprehend the nature of the disorder that the symptoms of the bromides are similar in their action to the disease process itself and it stands to reason that their administration is really more harmful than good. An absurd cart-before-the-horse principle is still in evidence in the prevalent belief that the fit in itself induces degeneration and that the bromides in temporarily checking the frequency of the fit really deter deterioration. Aside from the use of bromides for diagnostic or emergency purposes they should be entirely discarded in the treatment of epilepsy. What are their chief or alleged attributes for a continued therapy in epilepsy? It is said they quiet and tranquillize the patient and in that manner lessen the stress of life for him. How much better this can be accomplished by understanding the epileptic's individual problem, his opportunities and his handicaps and thus help him to revisualize them and make his peace from within naturally and not by a chemical substitute.

In conclusion, we may say that the drug treatment at best fulfills little, least of all to promote an enduring arrest of the seizures in epileptics, and when one who has this complete goal in view feels that in itself any drug is a failure, he is not far from the truth. This is especially true if a sedative plan solely is followed but combined with other supportive treatment the picture is less gloomy. The maximum of drug advantage is secured if they are employed as adjuvants to an otherwise more embracing therapy. The greatest and surest permanent benefits are obtained when sedation is held to the minimum and supportive and restorative remedies are mainly employed. Even then the vanishing rôle of drugs in the treatment of the epileptic is broadly stayed, for the dawn of a better system of therapeutics is well on its way, indicated in the more dynamic aspects of treating the epileptic organism *in toto*.

Neurosis and Total Personality*

FRANZ ALEXANDER, M.D.

Berlin

(*Continued from page* 166)

They also had the foreboding that this disease had a purpose which was to loan some justification to the asocial isolation of the patient. That many a physician believed that nothing ailed the neurotic and treated her with impatience and lack of sympathy, is the reaction to this unconsciously understood secret meaning of the disease. The pure fact of suffering therefore acquires the greatest economic rôle in hysteria because therein the material sense of the symptoms often falls short of the need of punishment.

In the nosological limitation of the neurotic character I have described a similar regularity. While the neurotic in his symptoms is alike unmoral and overmoral, his character in its conduct of life is alternately near to criminalistic and suicidal. He does not live his aggressions and his social tendencies in symptoms but in actions, although in contrast with the criminal he does not look forward to retribution on society but is himself his own judge.

Just as impulsively as he has yielded his asocial tendencies he resigns, although unconsciously, tendencies in difficult situations of life and he himself is the secret director of the tragic justice of his fate. He acquires, as did one of my patients—thanks to his impulsive lack of inhibitions—great wealth in order with his iron regularity, under pressure of conscience, to lose it again with equal rapidity. Then the play began again, prosperity and poverty alternated in his existence and from the same motives, just as certain neurotics show manic and melancholic periods.

I have been able to study this significant and regular association between the desire for punishment

*Read before the IX International Psychoanalytic Congress, at Homburg, September 3, 1925.

and repressed psychic content most clearly and in all its details transparently in dream pairs and dream series which often recur in the same night. Since my article on this subject, published in Vol. XI of the *Internationale Zeitschrift,* the number of examples of such economically associated dream pairs has greatly augmented. I would like to repeat only the result of my investigations. Very often among these dream pairs one is a dream of punishment while the other is a specially distinct wish dream (often a pollution dream) with ego foreign content. The economic connection between both is extremely close and consists of the fact that the punishment dream makes possible the occurrence of the wish dream, since through the punishment dream the desire for punishment is immoderately satisfied, and the repressed tendency, free, often hardly masked—for the censor is no longer disturbed by moral scruples—can come to expression. In other cases again the succession is inverted. After a distinct wish dream with ego foreign sense, a moral tension—so to speak—persists, which is led off into a punishment dream. I would like to express this thus—just as a man with an unsatisfied repressed wish cannot, with a bad conscience sleep tranquilly. The bad conscience which possesses just such dynamic power as an unsatisfied wish must first, in its sense of justice, be satisfied with a punishment dream in order not to be disturbed further in sleep. This is the simplest explanation of the punishment dream.

However, life often furnishes a crass confirmation of this regularity. A neurotically diseased person was run over and badly injured by an auto through a misdeed with intent directed against his own person. On the next day not only was his depression gone but hatred against his father, long held in check, broke through unrestrained. "Now I have paid for all," he said, "now I will speak my mind freely to my father." He at once would demand his inheritance from his father. The suffering which he had undergone removed all bounds from his repression, the selfpunishment delivered him from all feeling of indebtedness towards the father, which until now had inhibited his aggression. The debt had been paid by suffering.

In a patient with a severe compulsion neurosis of ten years duration spontaneous recovery set in when he secured from a relative a subordinate and poorly paid situation and by strenuous work was able barely to support his family. This relative who stood in the centre of his guilt complex and was bound to him by unconscious envy (a repetition of the father conflict) duly made the most of his masochistic devotion. So long as he supplied the work of a slave he was free from every symptom and fell ill only when his luck had turned and he had become independent and had attained a materially and socially advantageous status. His conscience did not grant him the free, careless life, but sought after punishment, hitherto his lot, and when this failed him provided the neurosis. In such cases one really obtains the impression that the neurotic inescapably bears his cross in some form.

Thus are explained the sublime results of healing of the evangelists—the sick men have been freed from the oppressive feelings of guilt. Christ, who assumed the guilt of all mankind, freed it from suffering. In the soul guilt and suffering are inseparably united. The moral centre may be called a specific centre of force, a dynamic factor and in order to understand mankind we must become acquainted with its expressions, just as with the expressions of repressed impulses which are inhibited by this moral centre. Freud gave the classical formulation of this fact in the sentence "that the human being is not only more unmoral but more moral than he himself believes." The consideration of mankind from the purely libidinous side gives a one sided picture. If my assertion proves to have been correct that the neurosis, and indeed every neurosis, rests on the pathological relation of the repressed instance to that which is repressed, the special knowledge of this disturbed relationship receives an eminent therapeutic importance.

The first comprehensive essay based on the ego theory of Freud to present the importance of the wish for punishment is the admirable work especially serviceable for the development of the ego physiology by Reik (*Confession-compulsion and Punishment-need. International Psychoanalytic Library.* No. XVIII).

Reik sees in the compulsion to confession a compromise performance between the urge for expression of the repressed and the need of punishment. The confession is an avowal of guilt and leads to punishment. The particularly interesting result and the finest psychological observation of his investigation is that the criminal with his open avowal of the sin to the inner psychic judge, the superego, which is secretly conjoined with the repressed tendencies, substitutes for the external judge and therewith accomplishes the stride to society. But the symptoms of the neurotic in so far as they signify a confession hidden although miscarried, for the entourage unintelligible, contain at least the effort to renounce by this selfbetrayal, the asocial shutting off. With the confession one refrains from bare criticism of one's superego and exposes himself to criticism by his fellow man. Even if our feelings according to Reik overvalue the confession character of the neurotic symptom—the compulsive neurotic for example betrays his symptoms unwillingly—his activities signify an essential deepening of the psychology of the neuroses.

The type of these relations allows itself to be reconstructed on a basis of the quite crudely presented facts of the neurosis and dream doctrine. Especially the dream pair, but also the build of the symptoms of compulsion neuroses, the economic importance of suffering in hysteria, the periodicity of manicdepressive conditions, the turns of fate of the neurotic character force upon us the sense of this connection. The overmorality, the overausterity of the neurotic conscience stands so in the service of repressed tendencies that the punishment required by it, the suffering, the masochistic contrary sense of the symptom, furnish the moral justification to the eruption of the suppressed. Its overausterity and injustice inwardly, which so much limits the action radius of the neurotic in life, leads to an overheated, revolutionary atmosphere in the soul. The neurotic symptom is an attempt at disburdening which stands closer to the claims of the it.

Practical Therapeutics

Psychological Factors in the Treatment of Disease, with Especial Application to the Treatment of Paralyses in Childhood*

HENRY KELLER, M.D.
New York

(*Concluded from page* 150)

The boy, on the other hand, will choose more hazardous games looking for an outlet of greater energy, more courage and more combativeness. The plays most dear to the heart of all boys are running, jumping, climbing, skating, wrestling, flying kites, building bonfires, etc.

It is in the selection of the varieties of games and in the methods of approach that the ingenuity of the physician displays itself, and upon this depends whether the attempt will be crowned with success or prove to be a dismal failure.

Even natural tendencies of childhood can serve as a guide and aid in restoring some lost function resulting from injury at birth, i. e., Erb's palsy or obstetrical paralysis of arm.

FIG. 3.—S. G. Baby, aged thirteen months with Erb's paralysis of right arm engaged in active calisthenics.

Vilhelm Rasmussen (11) in his interesting work dealing with child psychology, when speaking of movements in the child, calls attention to the fact that though the hand movements of the quite young infant are entirely indeterminate and spontaneous, it is also easy to provoke reflex movements. If one lays a finger in an infant's hand, it curves the fingers together, closes the hand, and it has relatively great strength in its fingers for it often can hang by them, supporting the weight of its body. The child also closes its feet, if one may use the expression, when one places a finger beneath the toes. Such action can be seen in a child in the first few months. From the spontaneous or reflex movements with the hands there is a steady transition to uncoordinated and badly controlled but voluntary movements, and thence on to well coordinated, surely controlled, voluntary movements, as when, for example, the child grasps its feeding bottle with both hands and guides it to its mouth. Such function can be seen present in a child of about six to seven months.

That these functions in childhood which are natural can be induced to serve our purpose can be seen by all without further elaboration.

NATURE OF TOYS

Children seem to be peculiarly susceptible to bright colors, musical instruments and objects in motion. For female children—a doll colored and which makes a sound when squeezed is very acceptable. A rubber ball suspended and in motion is attractive to both sexes, and will usually elicit a response in children of very young age. A musical instrument in need of winding up in order to elicit sound or one in need of a stick to touch the keys in order to create music can be used with advantage. "According to available experience," says Rasmussen (12), "babies, as a rule, have a great feeling for song and music."

Other important considerations in need of elucidation before their significance can be grasped are

DISTANCE AND COLOR PERCEPTION IN CHILDREN

Baldwin cites experiments conducted on his own child, since the child was nine months old, with reference to the determination of distance and color perception, and he tabulates his findings as follows:

The colors range themselves in the order of attractiveness—blue, red, white, green and brown. Disregarding white, the difference between blue and red is very slight compared with that between any other two. Brown seemed to be as neutral as could well be. White, on the other hand, was more attractive than green. The newspaper was, at reaching distance (nine to ten inches) and up to fourteen inches, as attractive as the average of the colors, and even as much so as the red. At fifteen inches and over the newspaper was refused in ninety-three per cent. of the cases, while blue was refused at that distance in only seventy-five per cent. and red in eighty-three per cent.

FIG. 4.—M. K. Had infantile paralysis of inverters of both feet grasping a tinker toy with his big toes.

The child persistently refused to reach for anything put sixteen inches or more away from her. At fifteen inches she refused ninety-one per cent. of all cases, and ninety per cent. of color cases, and ninety-three per cent. of newspaper cases. At nearer distances we find the remarkable uniformity with which the safe distance association works at this early age. At fourteen inches only fourteen per cent. of all cases refused, and at thirteen inches about seven per cent. There was a larger percentage of refusals at eleven and twelve inches than at thir-

*Lecture delivered at the University of Bellevue Hospital Medical College February 5, 1926, under auspices of the Neurologic and Orthopedic Departments.

teen and fourteen inches when brown was in the group of the former. Brown was refused considerably when more than ten inches distant. The fact that there were no refusals to reach for anything exposed within reaching distance (ten inches) other attractive objects being kept away, shows two things, 1, the fine estimation visually of the distance represented by the armlength, and 2, the great uniformity at this age of the phenomenon of motor suggestion upon which this method of child study is based.

Fig. 5, a, b.—M. G. Nine years old. Infantile paralysis of left arm, illustrating play method of stimulating shoulder and arm muscles to function.

These conclusions are based upon the results of 217 experiments. Three of these were with five colors and 106 with ordinary newspapers.

The application of the above rules in my own cases, suffering from Erb's as well as infantile paralysis, has been of immense benefit to my patients and of great interest to me.

Before commencing my treatment I make it a rule to test the distance of response of the normal and abnormal limb for comparison. Color and sound attraction and general responses.

The observation as to whether the visual or auditory sense is more developed is of great importance, and the games are devised accordingly.

The animistic tendency of early childhood (the tendency of the child to imbue inanimate objects with life) is another of those habits which can be easily made good use of in treating children up to four years of age. In boys, animals to play with are preferable, and even rubber balloons of all fantastic shapes, and representing all kinds of creatures belonging to the bestial kingdom, will be welcomed by them.

The tying and bandaging of the normal arm to the body and then urging the child on to catch a toy with the affected arm is a very effective way of stimulating a partially paralyzed limb to activity. In attempting to interest the child in the various games and to get the child to benefit most by them, the following rules must be understood:

The child is peculiarly susceptible to the appeals of change, novelty, chance, or happy suggestion, and often the failure to respond to a stimulus is due to distraction, or to discomfort, rather than to the lack of intrinsic interest.

Fatigue should be avoided and the first sign of restlessness or loss of interest on the part of the child should give us a warning to stop.

Baldwin gives the following sound advice: that after each effort or two the child should be given the object reached for to hold, or play with for a moment; otherwise, he grows to understand that the whole affair is a case of makebelieve.

The response of the child depends upon the physical condition that it finds itself in, and any change from the normal should be a sign to postpone the treatment for a time more opportune and when the child will be in a more responsive mood.

In conclusion, I feel that Ely's advice with reference to the examination of a child suspected to be suffering from tuberculosis of a joint shows very forcibly the need of the knowledge of psychological principles in relation to the child, and deserves to be repeated verbatim.

"As a rule," says Ely (13), "all necessary manipulations can be made with the slightest amount of pain or with none at all. It is not advisable to strike the patient forcibly upon the head or heels. There are some children (and some parents) so refractory that their examination will always be unsatisfactory, but if one uses tact and patience one will find their number very small. Sometimes a postponement to another day will soothe their fears. One should make it a rule never to inflict pain on a child if it can possibly be avoided, and never to deceive him, especially if he is to be seen again. Frequently a running fire of remarks well interspersed with questions will divert his attention completely. Occasionally a child is met who objects strongly to the removal of its clothes, but if the clothes are admired and an inspection of them be requested, he will part with them readily. Most boys resent the title of "My little man."

Once a child's confidence is gained, the rest is easy.

A child is the most tractable creature if one learns how to handle him, and to know the child's mind is the most essential part of our mental equipment in the treatment of disease.

In conclusion I want to express my appreciation to R. H. Sayre, Edward D. Fisher, and David E. Hoag for their courteous cooperation.

Anticonsumptive Therapeusis.—R. Hervé (*Lancet,* January 17, 1925) believes that, setting aside all treatment by drugs, among which the doctor, nevertheless, will often find helpful tools, at the present time all pulmonary tuberculosis cases where suppuration occurs as revealed by the ear or the screen—or even where the disease is in rapid evolution—should have recourse to a Forlanini operation. Pulmonary compression will work wonders, provided that it be properly carried out. To achieve this purpose, and in order to make up for any possible insufficiency of compression, the author inaugurated the method of dividing pleural bands. But, besides such surgical measures, the simple and fundamental methods of treatment must never be overlooked—namely, rest, open air, and sunshine.

Historical Medicine

Skin Pathology in Ancient Medieval and Modern Times

SAMUEL GORDON, M.D.

Philadelphia

The theory of evolution and involution governing the entire universe is not a product of recent conception and adoption. The ancient philosophers anticipated it, the scientific investigators have had a mental perception of it, and the students of natural history have been perfectly acquainted with it.

A beautiful allegorical expression in the Talmudic literature, characterized by its condensation of language and depth of thought, suggests fairly well the belief of the men of those days in the above named theory. Elijah, the prophet, was asked, "What is the Eternal God doing?" and his answer was, "The Eternal God is sitting and building worlds and destroying them." Note that the passive verb "is sitting" denotes that the Eternal is not hurrying and indicates the immense periods of time consumed in the process of evolution and involution.

The antronomer sees the construction of celestial bodies in the unresolved nebulæ or cosmic vapor and the destruction of planets and comets in the meteors and asteroids.

The geologist perceives a similar process in the aqueous and igneous rocks. He counts fourteen systems between the Laurentian rocks, the oldest on earth, and the Alluvium ones of the present time.

The botanist attributes this theory to every member of the vegetable kingdom from the thallophytes to the flowering plants.

The zoologist finds the same process in the animal kingdom from the protozoa to the mamalia and man.

The historian relates of nations and governments following the periods of development, fastigium, and decline.

The physician observes the same rule almost in every disease afflicting the human being.

It is, therefore, very logical to deduct that the same process equally applies to the disease producing microorganisms. In other words, bacteria that have produced certain diseases in ancient times are not existing at present and vice versa.

To prove that such is actually the case I will discuss several diseases bearing the title "leprosy." I shall consider leprosy of the Bible, lepra Arabum and lepra Graecorum.

LEPROSY OF THE BIBLE

The septuagintal translation of the disease *zaraat* described in the Levitical text by the term leprosy has been a misfortune. It has caused much confusion in the medical world. Almost every dermatologist was more or less under the impression that lepra or elephantiasis arabum and lepra græcorum are akin to the leprosy of the Bible. Even some of the modern dermatologists are still under this erroneous impression. A question which seems to have puzzled every dermatologist arose—how the garments, leather goods, and walls of houses came to partake of the infection of leprosy.

Gregory Hostius, a famous physician of his time, makes an attempt to cover this naked ignorance with a religious mantle. "As the Supreme Being did grant unto the Israelites very particular blessings and singular privileges so did He punish their ingratitude and abuse of His favors with very severe and singular judgments."

Dr. J. F. Schamberg, a famous dermatologist, in his fascinating contribution to the *Jewish Encyclopedia,* under the term leprocy describes the following four cardinal symptoms of the disease *zaraat* mentioned in the Bible.

1. Bright, white spots or patches on the skin, the hair of which was also white.
2. The depression of the patches below the level of the surrounding skin.
3. The existence of "quick raw flesh."
4. The spreading of the scab or scale.

He further expatiates on the differentiating points between this disease and modern leprosy and proves very logically that the two diseases have nothing in common.

Finally, he comes to the conclusion that "the white spots, upon which so much diagnostic stress was laid, were in all likelihood those of vitiligo, a disease quite common in tropical countries and characterized by bright, white spots the hairs on which also become white." But why should a noncontagious disease such as vitiligo be isolated? He answers this question in the following words, "There is much reason to believe that the segregation of lepers was regarded at any rate at certain periods more in the light of a religious ceremonial than as a hygienic restriction. *Zaraat* was looked upon as a disease inflicted by God upon those who transgressed His laws, a divine visitation for evil thoughts and evil deeds." "Lepers were obliged to remain outside the camp because they were regarded as likely morally to infect others."

The writer of this article finds it absolutely impossible to associate the *zaraat* of the Bible with vitiligo. The reasons are as follows:

1. Vitiligo is characterized by milky white patches; *zaraat* is a snow white lesion. Almost every place in the Bible where *zaraat* afflicting man is mentioned, it is specified "white as snow." Exodus Ch. 4, V. 6: "And the Lord said furthermore, unto him (Moses) 'Do put thy hand into thy bosom' and he put his hand into his bosom; and when he took it out, behold, his hand was leprous, white as snow." Numbers Ch. 12, V. 10: "And the cloud departed from off the Tabernacle; and behold, Miriam became leprous, white as snow." Kings 2, Ch. 5, V. 27: "May then the leprosy of Naaman cleave unto thee, and unto thy seed forever, and he (Gehazi) went out from his (Elisha's) presence a leper as white as snow."

2. The literal meaning of the Levitical text describing the second symptom does not indicate depression of the patches below the level of the surrounding skin. It signifies a deeper involvement, a penetration of the lesion to the muscular tissue beneath the skin. Similar to the disease "leuce" described by Hippocrates and Galen in which the chief diagnostic feature of its contagiousness was based upon the involvement of the muscular tissue. Furthermore, the primary lesions of *zaraat* were *seet* and *baheret*. The meaning of the first is an elevation, the formation of a papule or a nodule. How then, can there be an elevation and a depression at one and the same time? "Baheret" in a macule, which has neither elevation nor depression.

3. Vitiligo or leucoderma is usually slowly progressive in its course and seven days or a fortnight would show absolutely no change. *Zaraat* was a rapidly progressing disease. The examinations are prescribed to be made at intervals of seven days each.

4. Vitiligo is very rarely cured, while *zaraat* was a curable disease. When the leper was cured, he was ordered to bring offerings to the Lord.

5. Vitiligo is recorded separately in the text as a noncontagious disease. Leviticus Ch. 13, V. 38 and 39: "And if there be a man or a woman having in the skin of their flesh bright spots, white, bright spots, And if the priest do see and behold there are in the skin of their flesh bright spots, pale and white, it is a freckly eruption grown in the skin; he is clean."

If the segregation of lepers afflicted with *zaraat* was not a hygienic restriction and the adjective tame (unclean) denotes only that the leper has transgressed the laws of God; if such be the meaning of *tame* then we have to assume that the swine, the camel, the hare, the coney, and the fishes without fins or scales, forbidden to be eaten because they are tame, means that these animals have transgressed the laws of God. Shame on them.

The worthy contributor corroborates his statement by bringing evidence of four cases mentioned in the Bible who have transgressed His laws and were punished by *zaraat,* namely, Miriam, Joab and his family, Gehazi and King Uzziah. A cross examination of these cases reveals just the reverse. Miriam uttered disrespectful words against God's chosen servant, Moses. So did Aaron. Numbers Ch. 12, V. 1: "And Miriam and Aaron spoke against Moses." Why was not Aaron afflicted with *zaraat?*

Joab and his family were cursed by David with leprosy for having treacherously murdered his great rival Abner. We do not find in the Bible that this curse has been fulfilled.

Gehazi provoked the anger of Elisha by his mean covetousness. It is more reason to believe that Gehazi attracted the disease through the garments he received from Naaman. (Kings 2, Ch. 5, V. 23.)

King Uzziah attracted leprosy because he sacrificed incense on the *Bamah.* His father Amazyah and his son Jotham did the same. In fact this was the custom of those generations. All the people of Israel have practiced the same, yet no one else attracted leprosy.

The Bible placed *zaraat* in the same category with *zab* (specific urethritis), and pronounced a verdict of excommunication upon the person afflicted with it because it is a contagious disease similar to the contagious diseases which require isolation at the present time.

A thorough crystallization of the Levitical text translated into modern medical language reveals the following description: *Zaraat* is an acute, subacute or chronic, highly contagious and infectious disease characterized by the appearance of snow white macules, papules, nodules or scales (*Sapahat*). The exciting cause is probably a fungus of high virulence acting upon individuals whose resistance is below par.

The virus enters the blood stream, multiplies and forms emboli which deprive the part of its vascularity, thereby producing a least resistance in the tissue affected. The action of the liberated toxin upon this debilitated tissue manifests itself by converting the natural pigment into a snow white appearance involving skin and hair. As the disease progresses, the lesion extends to the muscles below, new lesions are formed and in the severe type a spongy morbid excrescence is developed. Two types are mentioned in the Bible:

An acute type which runs a comparatively short course and terminates either by recovery when the patient's resistance is good, or by death in debilitated persons. The first two symptoms—the color of the skin and hair, and involvement of muscular tissue—were sufficient to pronounce the case contagious. In the cases where the muscles were not afflicted and the hair did not turn white, the diagnosis rested mainly upon the spreading of the lesions to other locations. (Leviticus Ch. 13, V. 1-8.)

The chronic type was diagnosed by the formation of "quick raw flesh." In this type there was no involvement of the muscular tissue. The breaking out of the disease in other parts of the body without forming quick raw flesh was not considered contagious. (Leviticus Ch. 13, V. 9-17.)

Zaraat had a predilection for scar tissue, especially scars of wounds and burns. The scalp and bearded region were occasionally involved. The symptoms in these cases were similar to those described above except that the scalp cases were yellow in color and in healed inflammatory spaces the lesions and hair were of a reddish white color. (Leviticus Ch. 13, V. 18-58.)

There was one type of *zaraat* which had a favorable prepossession for linen or woolen garments, leather goods and walls of houses. The Bible terms this fungus *zaraat Mameret.* It was very virulent and capable of attacking susceptible persons through mere contact. The ordinance prescribed in the Bible to burn the garment and destroy the wall contaminated by *zaraat Mameret* is sufficient evidence of its high virulency.

The origin of *zaraat* is obscured. Its period of development must have been in the prehistoric time. It reached its fastigium during the dynasty of the Pharaohs of Egypt; at the era of the Bible the disease began to undergo its period of decline and at the time of the Talmud the disease was extinct.

The Talmudic literature discusses several noncontagious diseases entirely different from the *zaraat* of the Bible. They link their diseases with *zaraat* because of their traditional custom to link all their teachings, advices and moral sayings with certain passages of the Bible.

Importance of Pathology in Prevention of the Diseases of Childhood

DWIGHT M. LEWIS, M.D.

New Haven, Conn.

The importance of pathology in diagnostic medicine is not to be questioned: its use in the interpretation of signs and symptoms, for diagnosis, for treatment, and at the postmortem table as well is fundamental. Pathology as applied to preventive medicine is a little studied art. That it is as fundamental in preventive medicine as in diagnostic medicine may be definitely shown. Its recognition has been neglected for two primary reasons. The one is that standard public health practice even at this time recognizes that with some exceptions the spread of the communicable diseases of man centre entirely upon the case, missed or otherwise. A discussion of an exception is to the point. One may read recent health department bulletins from such a viewpoint. It is stated in the *New York City Health Department Bulletin* for January 2, 1926, that typhoid bacilli in typhoid carriers are the exception to the well known fact that "germs while actually producing disease are apt to be more virulent than while they are simply resting in the carrier stage." The reason given is that there is some actual disease of the lining membranes of the gallbladder and the bile ducts. To apply pathology to diphtheria and scarlet fever carriers as I have shown is to make no exception to typhoid and as in typhoid to demonstrate that the spread of those two diseases like typhoid radiates in the main directly from the carrier. The second primary reason in the neglected recognition of pathology in the prevention of communicable diseases is directly related. Bacteriology has been applied to the diseases of known etiology to demonstrate by the absence of the infecting organisms in the invasive or secretory discharges the termination of the disease as infective for others. To study in the field, the pathology of mucous membranes of cases and carriers of diphtheria and scarlet fever as has been done by surgery in the case of the gallbladder and ducts in typhoid cases and carriers is again to create harmony. In the sphere of communicable diseases of unknown bacteriological etiology also, current day practice in preventive medicine recognizes the presence during convalescence of socalled pathological discharges of importance in the termination of isolation. It is fortunate for the epidemiologist that the mucous membranes used for culture tests may be studied by the epidemiologist in the case of diphtheria or scarlet fever, in fact in all the respiratory diseases as contrasted with typhoid fever. The error lies very directly then in the viewpoint of the bacteriologist (as well as with the epidemiologist directing his work from the usual office desk). The viewpoint is well expressed in the health department bulletin previously quoted. It is as follows: "Cases of diphtheria can give rise to disease where carriers cannot for the reason of the enormous supply of germs present in the case." To follow in the pathological field the usual case and carrier of diphtheria is to find such a statement erroneous. Faucial diphtheria in the membrane stage will only too frequently fail to show the invading organism when cultures are taken from the membrane or from the throat secretions. Only when cultures are taken from beneath the presenting membrane are the best results secured. Should the case be laryngeal a total absence of organisms is the usual in cultures unless taken directly from the larynx. If on the contrary, there presents the usual picture of bilateral nasal discharge of the moribund or near moribund neglected case where there has been extension from the primary faucial lesion, one may sensibly as well as with a pathological appreciation of conditions, feel that in the latter instance we have to deal with the enormous supply of germs as is reasoned by the laboratory worker for any case of faucial diphtheria. Further, to follow actual cases of the disease whether reported or missed I may state that it is the rule that no spread of the disease arises in the family or in contacts until after the case has become a nasal carrier of convalescence. I have repeatedly called attention to the fact that whether case or carrier, positive throat cultures of themselves (of late years confirmed by virulence tests) are not followed by further cases. Early in our work we found that here and there among contacts of cases were to be found individuals with unilateral excoriating nasal discharges in no wise distinguishable from those of convalescent diphtheria. It was, however, to the point that these latter individuals were recent cases whereas the former indi-

viduals frequently gave no history of previous sore throats and had had the discharge for weeks even months. Had I not been familiar with the two sets of pathological nasal conditions, I should have, as it was my experience that physicians in general were very fearful of the similar nasal involvement of children convalescing from measles or less frequently from the other minor communicable diseases of childhood as indicative of diphtheria in the light of a positive laboratory report. I should, like the attending physician, even with normal throat and negative threat cultures have given, as I have seen physicians give, fifty thousand and more units of antitoxin without effecting the nasal discharge. And herein lies a further fallacious laboratory teaching of the day not borne out by field experience.

It is taught that a virulent diphtheria bacillus in passing from normal throat to normal throat gradually loses its virulence and only under such an unusual opportunity of being present in the throat of one developing measles or scarlet fever is diphtheria apt to develop. The field experience that is recurringly true whether measles, chicken pox, or other communicable disease of childhood is prevailing is that during or following convalescence of an individual in the family or in a neighborhood from measles par excellence, a well member of the family or a well contact of the convalescent case of measles develops diphtheria and the source of the latter disease may be found, as I have repeatedly shown, to be due to the nasal carrier convalescent from measles. Indeed, I have been able to show that a nasal carrier with negative virulence had a positive virulence during convalescence from an intercurrent attack of measles and was the cause of a case of diphtheria in an older brother, himself immune to measles. As is standard practice in typhoid prevention, the primary aim of prevention is the search for and the identification of the diphtheria carrier. I have found a further analogy with typhoid fever. As with that disease, the hedging in of the comparatively small number of carriers is a much more economical procedure than immunizing the entire population against the disease. Equally in both diseases it is a more responsible board of health procedure. In that diphtheria is essentially a contact borne disease as compared to the frequency with which typhoid fever is secondarily a water or food borne disease, immunization in both diseases is resultful mainly in the socalled upper classes. In diphtheria, as all will grant, it is with the lower classes so called that we have to deal. It is of little less importance in responsible prevention to remember that immunity in diphtheria is obtained only after upwards of a minimum of three months and in upwards of ninety-five per cent. of the children.

With years of experience one often has rather vivid "mind pictures" called into review in comparing responsible methods. The following one is ever recalled whenever I read that the prevention problem no longer is one of school age but lies dominantly in reaching the children from the age of one to five. During the closing months of a three years demonstration in a model health centre in the city a Schick test contest was held for school and preschool children. Upwards of 500 school and upwards of one hundred preschool children were given one or more preventive immunization doses of toxin-antitoxin. Before six months had elapsed, two children, both under age one, one each in two families, were dead of diphtheria. In each of the two families every other member of the family had been given a certificate either of immunity or immunization. In one family two such individuals were nasal carriers, one with a positive virulence. In the other family a single nasal carrier was found. The point at issue is that at the time of the Schick contests both of the children now dead were under six months of age and the mothers had been advised to wait until they had come "of age." With a morbidity of 107 and a mortality of fourteen for the year for this district called B, I would compare a similar metropolitan district A, of the city where nasal carriership was the essential routine. Both districts had had for years comparable morbidity and mortality rates. In district A for the first time I had during the year the entire services of one nurse. The morbidity in the district for the year was sixty and the mortality rate was two and five-tenths; rates gained in advance of any Schick testing in the district.

I have a further picture to paint as regards responsible health department preventive measures. It is recalled by the demonstration of a film on diphtheria prevention shown by a metropolitan city. With a child dead of the disease an inspector is seen ringing all the doorbells in the neighborhood, broadcasting the fatal event, the immediate need for diphtheria immunization, and where it may be obtained. In our city a film if made would show a nurse ringing doorbells but requesting to see all the children, looking for sore throats or missed cases, and nasal carriers. Any absentees are requested to be at the home the following half day or may be looked up at another address. The epidemiologist's history of the case often leads him to direct another nurse to a distant part of the city where immediate previous contacts may yield the causative carrier and rather immediately prevent further diphtheria cases in that area, otherwise untouched by the standard film. Whether the cultures taken to the laboratory are few or many, immediate and accurate results are to be gained in the prevention of diphtheria by application of pathology in the field under medical direction.

Statistics may well enter into the interpretation of some of the claims for diphtheria prevention by educational or Schick testing resultful campaigns. Today, Auburn, New York, is widely quoted as a proven instance of elimination of the disease as a result of a campaign in 1923. With a reduction in mortality from thirty-three in 1922 to five in 1923 and two and seven-tenths in 1924, there is no count made of the morbidity which for the respective years was 270, 120 and sixty. If we go back to 1908 we find that that city had a mortality rate of three and in 1912 one of five and seventh-tenths, with unknown morbidity rates. Since 1910 when morbidity rates are known the year 1912 shows one of twenty-eight. The city has a population slightly less than the cosmopolitan section of our city, district A, where I gained for 1923, as I have previously mentioned, a mortality of two and five-tenths in advance of any Schick work. Auburn's problem in 1925 was then one of reaching the preschool age for immunization. My annual report for the same year showed that

diphtheria cases under age five had been reduced thirty per cent. over the previous year as compared to the age group five to sixteen, where the percentage reduction was twenty-five. An outstanding fact was that of the entire content of three deaths for the city, one was in a temporary non-resident with infection gained without the city, one was a case of scarlet fever, and the third was in the age group five to sixteen. The outstanding fact was that for the first time on record, based on strictly residents and local infections as were under our jurisdiction, we were, in advance of educational Schick testing in the preschool age, without mortality in the age group under five years of age. In 1924, by the entire services of one nurse in the previously called health centre district B we obtained fifty-one per cent. of the total carriers for the year, obtaining a morbidity rate of sixty-four and a mortality rate of three and two tenths. In 1925 with a forty-two per cent. of total carriers corraled in the district we obtained a morbidity rate of ten and a mortality rate of zero. In that other comparable cosmopolitan district A for 1924 we reduced the morbidity from sixty-four to forty-two and the mortality from two and five tenths to zero. In this latter mentioned district, with approximately eight thousand grade school and four thousand preschool children, eleven hundred odd school and approximately ninety preschool children were immunized during the first half year. It may or may not be true that the procedure had an influence among those of school age: it is rather manifestly not true of the preschool age.

One may further read in the recently published annual report of New York City for 1924 that the Schick work for the results theorized in 1918 were not definitely satisfactory. To chart the yearly mortality rates by boroughs for that city from the year 1900 through 1925 reveals similar downward trends of mortality for the various boroughs for the periods 1900-1909 and 1910-1925 in terms of epidemic measles. Manhattan with a record mortality of eight and the Bronx with one of four in the year 1923, both went back over ten for the year 1924, a year of epidemic measles. The injection of pathology into diphtheria prevention has, in my twelve years of field experience, shown the interelation. With a minimum personnel of instructed nurses, epidemic measles in 1922 in this city was pathologically handled in five sixths of the city, resulting in not only cutting the *lowest* recorded diphtheria mortality rate in the city's history in half, but in continuing to yearly decreases as compared to the usual variations of increases during and following measles years.

Finally one may well reflect on the comments made in the 1925 annual report of Springfield, Mass. A record morbidity rate for diphtheria for the year of approximately fifty and mortality rate four and two tenths, "represents the effective cooperation of the medical profession in taking cultures from all suspected cases and using antitoxin immediately." "If toxin-antitoxin had been generally used, the forty-two per cent. reduction in cases would be so attributed." Unmentioned is the fact that the mortality rate was less than half of the next best records of 1911 and 1915, when the rates were approximately ten.

The application of pathology in diphtheria prevention will demonstrate the comparatively small number of carriers (previous articles on the subject netted us a two tenths per cent. carriership among the school population as compared to the usually published two per cent. where pathology was not mentioned) and promiscuous cultures, mainly throat cultures, were taken from groups of individuals and the results applied to the entire population. It is significant that rather generally over the country such procedures have resulted in a two per cent. carriership, although when virulence tests are carried out but one in ten of such show positive virulence. The end result is then the same figure as ours.

FORMER WORK

Ten years ago I published an article on scarlet fever showing the evidence at hand from field investigations that in nowise dissimilar fashion to diphtheria there were nasal carriers of convalescence and chronic carriers who had had the disease previously but at the later period were subjects of or convalescents from other intercurrent communicable respiratory diseases. 1. In the succeeding years I published articles giving the evidence that such nasal carriers of scarlet fever could be identified by a certain morphological streptococcus and related instances of where its use for diagnosis as well as for the control of an institutional epidemic was most satisfactory, 2, followed by an article showing the need for the differentiation of the various streptococci so usually found in throat cultures, 3. It was of import for not only identifying cases and carriers of true scarlet fever but for identification of cases and carriers of simulated diphtheria and scarlet fever. In a recent article, 4, I have been able not only to confirm the findings, but have as well, the definite explanation of the varying tides of socalled complicated specific diseases. Convalescent nasal carriers of socalled grippe were the common source of succeeding more virulent similar respiratory infections among contacts, and as well were the common source of severe, even fatal complications of scarlet fever for example, among nonimmune contacts when the carrier showed the further evidence of being a scarlet fever carrier also. It is little short of disconcerting to find how simple may be the explanation of the wherefor of simulated diphtheria in the case of a family where I was recently called in consultation by the attending physician. With mother and one young daughter ill with septic sore throat, a single look at the third member of the family, an older daughter, was to me, reasonable evidence of the source of the infection. The latter individual presented a unilateral purulent nasal discharge with excoriation of the upper lip, as pathological to look at as were the septic sore throats of the two bed patients. To the patients and to the physician this discharge developing during the last week of convalescence from mumps was of little moment in an individual to all intents perfectly well.

The illustration in my article on scarlet fever (2), showed a photomicrographic drawing of the streptococcus that I used morphologically for an aid in scarlet fever, of an ordinary streptococcus, and of a diplostreptococcus that I had frequently found in measles cases. One of the greatest of my distresses

for the past eight years has been that I have ever been unable to find a scientific technician who would prove the morphological diagnosis by serological and immunity work. The reply was ever the same: it would be of little value as compared to the work we are now doing in seeking an antitoxin and a toxin-antitoxin. I had, in my combined bacteriological and epidemiological work, become impressed with the frequency with which unknown endemic sources of measles might well be related to older children in the family at the time carrying pathological membranes of mouth and pharynx and frequent unilateral nasal discharges, the latter showing a predominant diplostreptococcus, easily distinguishable from other streptococci in morphology. The following incident impressed me as of importance. After our city was through with a measles epidemic, a local orphan asylum, hitherto well isolated by its location, started up an epidemic of the disease. The attending physician was a firm believer from previous experience in my method of preventing diphtheria after a first case appeared and the causal carrier immediately found by nasal inspection confirmed with the microscope. Upon inquiry as to what he might do in the best interests of upwards of five hundred children, I suggested that whether convalescent or immune every child with nasal discharge that was unilateral or other than a simple coryza be cultured on the principle that results in terms of gram negative diplococci or gram positive diplococci might well be isolated for a period with possible lessened or freedom from meningitis and pneumonia. The attending physician was afterward impressed with the absence of any pneumonia among the measles cases, attributing it to a number of individuals being isolated by reason of morphologically suggestive pneumococci and gram positive diplostreptococci. I was impressed with the fact that in a considerable number of cultures I found predominantly, the fine diplostreptococcus I had previously correlated with possible measles carriers. Without exception they were found to come from convalescent immediately previous measles cases.

EARLY WORK

I began my epidemiological work for the city in 1914, a year of epidemic measles. By the end of the following year I had my facts well in hand and termed measles, a blessing in disguise, in that I knew that through epidemic measles I could with a few enthusiastic workers reduce both morbidity and mortality from diphtheria. With epidemic measles on the horizon in 1917, I obtained the temporary services of two nurses and as has been related, (4), cut morbidity to nearly one-third and mortality approximately half that of similar preceding years and further reduced it the following year. There then ensued three years of work in other fields during which my successor followed the lines of least resistance and the measles year of 1920 again raised morbidity of diphtheria to the usual peak of former years with mortality not far behind. Again taking up the work at the close of 1921, I was "favored" with a measles year in 1922. With a fairly adequate personnel for work, I was able as I have related to gain for the first time during and following measles, a diphtheria mortality rate of five or less and to continue yearly to reduce it by teaching my personnel to seek "pathological noses." I had passed through the experiences of a camp epidemiologist for the "duration of the war," some six months after it was over and found much statistical material for 1917 and 1918 that could be charted. I was impressed with the sequence of measles, and broncho-pneumonia, and streptococcal infections of every variety in the rural camps as contrasted with their absence or the presence of lobar pneumonia in urban camps. Fitting my experiences together there was a reasonable lead that mortality in measles could be reduced if we could keep the sources of other complicating streptococci away. With the inability to distinguish by the eye acute nasal carriers of streptococci from those of diphtheria, with accumulated evidence that the streptococcal carriers were as potent for acute infections in others, even more so than diphtheria, a sensible factor seemed to be the corraling and isolation of such carriers before, during a measles epidemic and to have all children with measles treated in the home. I instructed my nurses to hold for cure every nasal discharge simulating a diphtheria carrier even though initial or continued cultures did not show the diphtheria bacillus. Epidemic measles of 1917 showed 1774 cases with 24 deaths, that of 1920 showed 914 cases and twenty-five deaths, the epidemic of 1922 resulted in 1869 cases with thirty-three deaths. The epidemic of 1925 yielded 1166 cases with five deaths over one thousand cases and the total deaths occurring during the first six months in an area, approximately one-third of the city. The remainder of the city was visited in the first six months of 1926 with a total of 1386 cases and three deaths. The controlled destructiveness of the last epidemic whether taken by single years or for both years is notable for two reasons. Firstly, case mortality rates were different from the usual one death to every one hundred cases at the most for any epidemic year. In 1925 in the poorer section of the city there was but one death to nearly 250 cases. For the past quarter century epidemic measles has claimed a mortality rate per hundred thousand of population of approximately twenty or greater. A certain portion of the more than quartered reduction in mortality, (none in morbidity), I feel is due to furnishing immediate medical services in the homes without questioning the seriousness of cases. Two questions may be raised at this point: many will say that as many or even more deaths primarily measles may have been hidden under a death certificate with pneumonia only as causal: others will suggest that during each year pneumonia was not the frequent complicator of other measles years. To the first question I may state that I personally make up the vital statistics monthly for the department and can rule out any error. To the second question I have also the assurance that epidemic grippe in May, 1925 and a greater wave in the first three months of 1926 gave rise to an unusually high pneumonia mortality. I have, in the absence of laboratory proof of definition and of virulence, no absolute proof that an excess of two hundred nasal carriers in 1925 and over one hundred in the first half of 1926 were the dominant cause of prevention of mortality. Of moment is the fact that the majority of the carriers were picked up in the areas where measles was appearing or in advance, on the edges of the burning area as

it were. The average time duration of carriership was rarely less than ten days, many being held for upwards of a month.

The use of scarlet fever antitoxin has been infrequent and the use of measles serum yet more rare.

As an attending physician to the bedside in hospital practice I was taught by the older type of practitioner to observe the color and consistency of the sputum of a pneumonia patient: the green blood streaked mucoid expectoration was suggestive of a laboratory report of influenza bacilli on smears; the rusty, purulent expectoration at the next bedside was a tentative aid in diagnosis of the pneumococcus: a thick purulent exudate from a pleural tapping was an expectant laboratory report of the pneumococcus and the forerunner of the handing over of the patient to the surgeon: a thin serous, little purulent, exudate from another chest tap was indicative of the streptococcal involvement and an indication not to operate. Likewise a study of the color of the tongue and the pharyngeal vault, together with the character of the accompanying or absence of coating of the tongue, meant a whole volume to the trained observer of experience before the days of bacteriology. Today the rank and file pass them by, relying on a laboratory report.

In public health practice of the socalled standard type there is the same milling around. The peaks and valleys of variations in morbidity and mortality of the specific respiratory communicable diseases are perhaps lower than a decade ago, and the standard teaching that case begets case continues theoretically well founded; personal hygiene and health habits have become the opportunity of teaching the public in those terms how to sidestep becoming a case. The handmaiden is the public health nurse instructing the individuals the procedures of quarantine and isolation of the case and epidemiology continues to be the office sorting of nurses histories for the common factor of infection, traced eventually to a case. We have travelled the road through in typhoid fever alone: here the first essential is to find the human carrier. We have gone a step further in typhoid fever: a responsible health department earns glory of results in cutting off the peaks of variations by seeking carriers in advance of cases. Responsible departments are more concerned with activities controlling the various paths typhoid infection may take to reach their public than they are in educating the public that by personal hygiene and health habits the public may dodge known infective paths.

CONCLUSIONS

1. Bacteriology as used in public health identifies and terminates, both cases and carriers of communicable diseases, by the presence or absence of the known infecting organism. Fundamentally it is the basis of the teaching that case begets case. When the pathology of the organs that are the seat of the infection are studied in carrier as well as in case, there may be found to be no exception in typhoid fever as compared to the more common respiratory diseases such as diphtheria, scarlet fever, and "grippe." The "enormousness" of bacterial content as well as the manifest contact path lies in these diseases as in typhoid fever, in the nasal carrier.

2. The single procedure of search for the diphtheria carrier when conducted pathologically, is resultful in finding nasal carriers of scarlet fever and of "grippe" at the least, if the bacteriological procedure of "negative for diphtheria" does not in turn, control the situation by the holding of diphtheria carriers only. The single procedure, isolating "pathological" noses for the duration of the pathological discharge, is resultful in immediate reduction of morbidity and mortality of diphtheria and of scarlet fever, and apparently as true in the mortality measles. In all three of the diseases, measles in the main, mortality reduction is gained by the reduction of the death dealing complications.

3. There is no evidence from the records of any city in this country that Schick testing campaigns, irrespective of the years in progress have, during or following epidemic measles years, continued to cut morbidity and mortality rates of the immediately preceding year or years. In no instance on record has there been gained a zero mortality for diphtheria in the preschool age group while such testing has been for one or more years carried out in the school population. In this city for 1925 where, at the end of the year, not more than fifty per cent of the school population had been reached by the Schick test, and no work had been done in the pre-school age, prevention of diphtheria by search for, and isolation of, diphtheria carriers, (gained from search for pathological noses only) gained such a record.

4. On the contrary, one of several similar areas of cosmopolitan races in this city, initiated a Schick testing campaign in the first half of the year 1923. For the year the morbidity was over one hundred and the mortality was fourteen. A comparable area where all the previous years of history showed equally high or higher morbidities and mortalities, had for the same year, and for the first time in its history, a morbidity of sixty and a mortality of two and five tenths. In the latter area prevention of diphtheria was limited to search for carriers. In the following year, in the last mentioned area, morbidity was reduced to forty-two and mortality to zero (all ages), although one-half of the schools of the area had not yet been reached by the Schick work.

5. By the application of pathology to the prevention of the common respiratory diseases of childhood, results are immediately gained in that class or classes of population as are at the same time, those most continually the sources of endemic disease and least often reached by purely educative programs. At the last analysis if reached in the greater per cent, they yet remain a source of the disease by the content of carriers.

6. Finally the application of pathology for the corraling of carriers of the communicable respiratory diseases is a medically responsible procedure, a responsibility of a health department that may well be asked for by the public.

Malnutrition in Infancy*

H. BROOKER MILLS, M.D., F.A.C.P.,
and SAMUEL GOLDBERG, M.D.
Philadelphia

In dealing with the subject of malnutrition we touch upon almost every abnormal phase of infant life. Digestion is so closely correlated to every other function that one cannot speak of any pathology or abnormality in infancy that would not touch upon child nutrition. Our purpose in this short review is more to deal with the outstanding etiologic factors, their prevention and removal if possible, rather than with the discussion of the physiology of digestion.

It is in the early recognition of the abnormal, and the ability to interpret Nature's warning, that we have our only hope in reducing the high infant mortality due to malnutrition.

The infant speaks in terms of bowel movements, of vomiting, of loss of weight, of restlessness, of abnormal or rather subnormal development—and the earlier these conditions are recognized and properly interpreted the greater are the chances for cure.

In the broadest sense nutritional disturbances are due to a disproportion between the nature of the food and the ability of the organism to digest and assimilate. (Abt).

We will consider the etiology of malnutrition as being due to one or all of three primary causes, as developed by Czerney and Keller: 1. Food. 2. Infection. 3. Constitutional anomalies or weakness.

Food as a disturber, because of modern modes of living, is becoming more and more a potent factor. No sooner is the baby safely tucked in its crib after birth, and the mother has regained enough strength to think of her social obligations, than she begins to look for excuses to give the baby a bottle, if not a complete weaning, at least one or two relief bottles, which to our mind is the beginning of a rapid weaning. The number of relief bottles soon tends to increase, for as the milk only appears in the mother's breast directly as it is made to do so by the periodical sucking of the baby, it consequently disappears in direct proportion as the function is omitted.

Of the artificially fed brought to our service suffering with malnutrition, overfeeding in quantity, quality and frequency has probably been the most common cause. At first the baby seems to gain, but soon digestive disturbances follow and every known proprietary food is tried. If the quantity alone is in excess, regurgitation and vomiting are early symptoms, but if the quality of the food is not well tolerated, these are followed by a train of symptoms depending upon which is the offender, namely the fat, the protein or the carbohydrate, while if frequency of feeding is the trouble, training of the mother is the only remedy. We will consider these quality factors in the order of occurrence.

Fat.—When this is given in excess of tolerance it usually causes vomiting, which occurs about one hour after feeding, and the vomitus is sour. It may also cause either diarrhea or constipation. When the bowels are loose the stools are acid, greasy, and green in color, containing lumps of fat and mucus. The acid in the stool is due to the fat breaking up into fatty acids, and these fatty acids irritate the bowel, increasing peristalsis, and diarrhea ensues.

When these fatty acids combine with the mineral substances of the body, and the mucus of the intestines, typical soap stools form, when, instead of diarrhea, constipation is present. The stools, when constipated due to fat, are foul smelling, whitish or grayish in color, very greasy and sometimes blood-tinged.

The urine in fat disturbance is highly ammoniacal, and alkaline in reaction, due to the excess amount of fatty acids entering the blood and being neutralized. Both the stools and urine are highly irritating to the skin.

Carbohydrate excess causes frequent watery, acid stools, accompanied by a great deal of flatulence and colic. Bacterial action causes fermentation to take place; this in turn increases peristalsis, and the fermentative diarrhea follows.

Protein excess causes symptoms mainly referable to the intestinal tract. Vomiting is rare, and, if present, is in the form of a large cheesy curd, which is not sour as in fat or carbohydrate excess. These vomited protein curds are tough, yellowish or whitish, and beanlike. The stools are usually constipated, although they may be loose and green, but do not have a foul odor nor irritating properties.

Total underfeeding, both in quantity and quality, also occurs very frequently. Occasionally a baby fails to gain on the amount of food which ordinarily satisfies another infant of the same weight and age. This depends on the baby being able to assimilate what it ingested. Insufficient amount of food ultimately calls on the reserve of the body, and inanition follows.

Even though these individual food elements are thus considered as causes, Finkelstein well emphasizes that these alone cannot be entirely considered as primary causes of nutritional disturbances. These disorders are rather the result of faulty correlation of the various elements. There is also some biologic property in human milk which is not found in cow's milk, and even though the elements in each be exactly the same, it must be remembered that milk is not only a food but a medium in which ferments and cells enact their digestive processes, and that these must be dealt with separate from the individual elements in the milk.

We next consider infection as a cause of malnutrition. The infection may be enteral, or that occurring within the alimentary tract, or parenteral, that taking place outside of the alimentary tract, such as influenza, furunculosis, otitismedia, bronchopneumonia, and other conditions. Enteral infections, even though predisposed to by previous nutritional disturbances, are usually followed by atrophy and marked intolerance for food.

Thus we have a food intoxication, fermentation

*Read before the Lehigh County Medical Society, November 18, 1925.

follows, infection sets in and then the usual picture of gut injury.

The occurrence of fever in these alimentary infections is believed by Moro and Hersh to be due to decomposition of protein substances, while Finkelstein believes that the fever depends upon dehydration of the intestinal mucosa.

It is important to be able to differentiate fever of alimentary origin and that of infectious origin within the intestinal tract. If the temperature is due to intoxication from food injury alone, withholding of food for about twenty-four hours will bring it down, but if, after withholding food, the temperature still persists, alimentary disturbances plus infection must be considered.

Lastly we consider constitutional defects. These, when present and unrecognized, cause the weight of the infant to remain stationary, in spite of sufficient quantity and quality of food. Vomiting, flatulence, restlessness and loss of appetite are all ascribed to the defects in the mother's milk, and the baby is weaned. Bottle feeding and various foods are tried, but the baby shows no improvement. Clinical observations show that it is neither the quantity nor the quality of the food, but the constitutional state of the baby that causes disturbance.

Exudative diathesis, as it is termed, is one type of constitutional disturbance. The symptoms in these cases are very similar; the children usually have eczema, a peculiar growth of the hair, a dry skin, are subject to colds, and usually have the socalled geographic tongue. With these cases the nutritional problem is very complex.

Another class of cases that does not thrive comprises those of neuropathic origin. Here the family history will show that all the children suffered in the same way, and that the parents have suffered from headaches, neurasthenia, etc. One can almost diagnose cases of this class as he enters the room. Abt so vividly pictures it when he says that the atmosphere is tense and sparkles. The mother is on her toes or "up in the air." She speaks in a highpitched voice, or fairly shouts, and talks rapidly and incoherently. In one breath she talks of her baby; in the next of her noble self, her suffering and discomforts, and her sacrifices. The father also is present, and he concludes his baby is on the brink of disaster, his business will be ruined, and his wife will become a nervous wreck. To complicate matters the near relatives take a hand, and shower their opinions and affections. This is the environment into which the baby with an already neurotic taint is placed.

Tuberculosis, syphilis, congenital rickets, pylorospasm or pyloric stenosis, endocrine disturbances, or in fact any form of congenital anomaly must be looked for as potent etiologic factors in malnutrition.

TREATMENT

Our most urgent message to you for the reduction of infant mortality from malnutrition is the conservation of human milk. Unless you are yourself aware of the problems of artificial feeding, you cannot hope to convince the nursing mother of her duties to her baby. Too often are we called to see an infant suffering with malnutrition where the obstetrician or midwife placed it on a formula at a moment's decision.

We plead for a greater cooperation between the obstetrician and pediatrist. It is not after the child has gone through the various stages of vomiting, diarrhea, loss of weight, and dehydration that our success in these cases is to be looked for, but it is before permanent injury to the infant's digestion and metabolism occurs that we may hope to raise a healthy baby.

Eliminating the first week's loss of weight by feeding the baby until the mother's milk comes in is, to our minds, highly commendable.

It is well, too, to inform the mother that it takes about two weeks for the maternal milk supply to properly establish itself, and it is during this time that the hygienic care of the mother, and of her breasts, will often determine whether or not the baby shall be breast or bottle fed.

When human milk is insufficient in quantity, we are of the opinion that complemental rather than supplemental feeding should be instituted. In other words we feel that if the mother does not supply a sufficient amount at each feeding the required amount of cow's milk should be given at once rather than replace a breast feeding by the use of a bottle.

The successful management of a case of malnutrition will as you see depend upon discovering the cause, and a careful history is a most valuable aid in doing this. From the history you will gather whether or not the child has been underfed or overfed; the kind of food; the hereditary taints; the hygienic surroundings; the method of preparation of the food; the frequency of feeding; the character of the stools, etc. Physical examination will reveal any signs of rickets, pylorospasm, tuberculosis, syphilis, degree of emaciation and dehydration, amount of excoriation, and determination of any focus of infection.

When dehydration is marked and vomiting has persisted our best results have been obtained with gastric lavage with five per cent. sodium bicarbonate solution, once or even twice daily, permitting to remain in the stomach after the lavage at least four to six ounces of solution. In more severe cases the intraperitoneal administration of normal salt solution has undoubtedly been a lifesaving measure. This must be done very carefully and with the most guarded technic. In about thirty cases in which this method has been employed we have only had one case of marked abdominal distention, probably due to a sterile peritonitis, but this quickly subsided.

For stimulation in these athreptic cases we rely mainly on brandy. Atropine has been invaluable in the control of the vomiting of pylorospasm and colic. We usually start with one drop of one to one thousand solution, but do not hesitate to push it to its full physiologic effect.

Calcium bromide in doses of from two to ten grains, depending upon the weight of the child, is given with excellent results in the highly neurotic type, and where intestinal pain and colic is severe.

An initial course of calomel, followed by saline, in cases where putrefaction and fermentation exist, we still find valuable in spite of many opinions to the contrary. We feel that the small doses do not have any irritating effect on the intestinal mucosa, but that it stimulates the flow of bile, thus inhibiting the bacterial flora.

Unless we are dealing with a "starch injury" we

usually commence with a barley water feeding on a two hour basis, and, if there be no carbohydrate intolerance, malt sugar is added. This we continue for a day or so, when, being governed by past history, we determine the kind of food to be given. Thus, if we think we are dealing with a case of fat intolerance or fat excess we will start the child on a skimmed milk formula, or, following the teaching of Marriott, we use lactic acid milk sweetened with light karo corn syrup.

Marriott has shown that cow's milk has a greater buffer value, i. e., that it takes more acid or alkali to change its reaction; therefore, it takes a greater amount of acid, which we are supplying in the use of lactic acid, to change the chyme to an acid reaction. This is necessary on leaving the duodenum to stimulate secretion formation and pancreatic secretion.

In some cases of fat intolerance, where skimmed milk is given but the child does not gain, we have followed Czerny and Kleinschmidt of Germany in the use of the boiled butter flour mixture, and with excellent results. This method of feeding is based on the theory that butter, when freed of its volatile acids by boiling, is assimilated in a high percentage when combined with whole wheat flour. We can thus feed them a high percentage of fat and still not have any symptoms of fat disturbance. Where the fat disturbance is mild the simple addition of lime water is sometimes sufficient to correct the trouble.

Of the carbohydrates our experience favors the malt sugars, although we occasionally employ the cane sugar in addition, where there is marked constipation.

Protein intolerance is probably the result of the child's inability to digest the heavy curd in cow's milk, and it is in these cases more than any others that the initial purge is most valuable.

Boiling the milk for two minutes tends to make the curd more flocculent and in some cases will relieve the condition. Jacobi advocates the addition of cereals to the formula. This is claimed to attenuate the curd, thus also helping to make it more flocculent.

When the simple addition of cereals and boiling does not correct the trouble pancreatization must be tried, and this can be done by the use of the peptogenic milk powder or the combination of flour ball and pancreatin in from two per cent. to five per cent. of mixture. Sodium citrate in doses of two to three grains in solution to the ounce of the formula has also proven of benefit.

In cases where we are dealing with fat intolerance to which an intestinal infection has been added an initial dose of castor oil should be given, this to be followed for twenty-four hours by weak tea sweetened with saccharin, or a cereal water. Here long periods of starvation should not be carried out. Calcium caseinate should be boiled and given with the milk, as this supplies the minerals for the combination with the fatty acids of the intestinal tract, so that saponification may take place and the irritation due to the fatty acids be overcome. In our experience cases associated with marked infection in the gut, plus systemic manifestations, are the most serious. There is a large area of absorption of bacterial toxins in the intestinal tract and many cases prove fatal within twenty-four to forty-eight hours.

Bismuth in large doses, tr. opii camph. and alkalies by mouth, and colonic irrigations should be employed. Suppurative measures are urgent from the onset.

In the type of malnutrition due to constitutional derangement codliver oil probably is most valuable. We advise starting as early as the third month with small doses given in fruit juice, increasing both as they are tolerated.

Iron mixtures are valuable in cases where there is a marked anemia.

Exposure directly to the sun's rays for periods varying from twenty minutes to one hour once or twice daily has been found to be a great stimulant to metabolism; so much so that, where the direct sun's rays cannot be had, the various quartz lamps or ultraviolet rays are being employed with excellent results, in cases of malnutrition of tuberculous origin.

This by no means covers the subject of the etiology and treatment, but if it has only emphasized the important points, particularly with an idea towards prevention, we will feel that it has served some purpose.

The Care of the Premature Baby*

WILLIAM N. BRADLEY, M.D.,
Philadelphia

Because of the brief space at my disposal this paper will be confined to a discussion of the treatment of cases of simple prematurity. Where other conditions exist, the picture becomes so complicated that each case must necessarily be considered individually.

Strictly speaking, all infants are premature who are born before the end of the normal term of pregnancy (forty weeks); in common usage, however, the term refers only to those infants whose gestation period was 260 days or less (3). Owing to the difficulty of definitely fixing the date of conception, it is impossible to determine accurately the degree of prematurity of the infant. As an aid to this end various studies have been made of weights of the fetus at various stages of development, and time of development of ossification centers, but no satisfactory standards have yet been evolved. In the case of foundlings, where all data are absent, the degree of prematurity becomes still more a matter of conjecture.

In so far as the length of gestation is concerned, a fetus of six months or less is not viable; the mortality of those infants prematurely born at six or seven months has been given as eighty per cent. and, those born seven to eight months forty-four per cent. (4).

From this point upward the infant's chances in-

*Read before a combined meeting of the Philadelphia Pediatric and Obstetrical Societies, November 10, 1925.

crease with prolonged intra-uterine life, when by the thirty-eighth week the mortality drops to eight per cent. (2) unless the infant is handicapped by the presence of other factors.

Mortality the first day of life has been estimated as fifty-seven per cent. (4).

From the standpoint of weight, a fetus of 720 grams is the smallest that is known to have survived (7). Cerebral and spinal hemorrhages are frequently found in those babies weighing less than one thousand grams and these are one hundred per cent. fatal; as well as those who are victims of hemorrhagic diathesis or atelectasis.

No general law of averages, however, can assist us in the care and management of the individual premature baby. We are able to say that below a certain age or weight an infant cannot survive, nor yet, in the presence of certain conditions, but beyond this each baby becomes an individual problem.

The causes for the premature expulsion of the fetus will not be discussed at this time, except in so far as they relate to remediable conditions in the fetus.

The general appearance of a premature baby varies with its fetal age, but in general, it is a small puny infant with angular features, thin soft skin, palid or vivid red, hanging in folds through which the blood vessels are distinctly visible, with scant adipose tissue.

With the lengthening of fetal life, these characteristics become less pronounced, and the fetus approaches the appearance of a full time infant. Any attempt at estimating mortality percentage should be done by group classification according to conditions present.

The adequate care of such a baby demands the same preparation for its birth as is required for an emergency operation; always remembering that every hour that can be added to its life increases its chances for ultimate survival. This preparation will concern first the new environment into which the baby is thrust. It should be received immediately into blankets, surrounded with hot water bottles, and placed temporarily in some form of incubator.

A premature invariably has a subnormal temperature, is susceptible to changes in the temperature of its environment, and radiates comparatively more heat than a baby of normal size (5). For this reason exposure while dressing the cord should be avoided if possible and measures instituted to sustain body temperature, but in the presence of asphyxia, cyanosis and atelectasis exposure is sometimes unavoidable.

As soon as convenient, the weight and other important data should be recorded, the baby oiled, a compress diaper applied, and the baby again wrapped in a special jacket; as the premature baby possesses greater susceptibility and but feeble resistance to infection, strict asepsis is imperative.

When possible the room selected for the premature should be sunny and provided with proper heat, ventilation and moisture. Elaborate premature rooms have been constructed in some maternities, which meet these conditions and are regulated automatically. Such installation is expensive and rarely practicable.

Every effort should be made, however, to approach such an environment. The temperature of the room should be maintained at 80° and the humidity 55-60 per cent.

Many forms of incubators have been devised, which vary in construction from a simple bed, to complicated devices, regulated to automatically provide fresh, warmed, moist air.

For practical purposes, in the average maternity a nursery bassinet, arranged as follows will, I believe, meet all requirements: In the bottom of the bassinet is placed a mattress and the sides are lined by a blanket covered with sheeting. About three inches from the top of the bassinet, on the inside, a blanket is stretched tightly from side to side. Under this blanket, on which the baby lies, is placed two metal trays; one to hold a forty watt electric light bulb protected by a wire cage, and another to hold water. Across the top, three-quarters the length of the bassinet, from the baby's chin downward, is stretched a blanket and sheet covering, and a similar one upward to the top of the bassinet, leaving a space between for the circulation of air and for the nurse to observe and care for the baby. The head should always be kept covered. A thermometer placed alongside the baby under the blanket covering is charted every fifteen minutes by the nurse. An attempt is made to maintain the temperature of the bassinet at 90 to 100°, if the baby's temperature is 96° or below, and as the baby's temperature approaches normal the temperature of the bassinet is reduced. The room temperature should be kept at 80°. The bassinet temperature is regulated by the nurse, who turns the light off should the temperature rise above a fixed point and turns it on again to maintain that degree of temperature. The air in the bassinet should be continuously warm and moist.

Subsequent care will include maintenance of even room temperature, protection of the baby from shock, thermal and mechanical, the skin from contagion or injury, and the eyes from light. The baby should be disturbed only when necessary for oiling and change of gauze diaper (5). It is advisable, however, to change the position of the baby occasionally to avoid congestion of the lungs, and in the presence of atelectasis.

The question of the nurse is important. She must be competent, interested, realizing her responsibility, and willing to make sacrifices. She should be prepared to meet any emergencies which may arise, overcome the difficulties of feeding technique, and combat asphyxia and cyanosis.

Initial loss of weight in the premature is relatively greater than in the normal. These babies regain their birth weight more slowly, twenty to thirty days (1).

Feeding the premature baby is beset with the same difficulties as feeding the normal baby, but to a greater degree.

It becomes apparent very early that it is difficult to supply sufficient food to the premature baby to meet its caloric requirements. In order to save these babies, it is necessary to push the feeding to the limit of their digestive capacity.

Sufficient nourishment should be ingested to insure growth and maintain body temperature, but the gastric and digestive capacity is small, as against a high caloric requirement, which for the premature is distinctly greater than for the normal baby, 140-160 per

K. (4). The more premature the baby the more feeble its digestion. Metabolic processes are slower and loss of heat relatively greater than that of a full time infant. Tolerance for sugar appears to be greater than for fats and proteids (9).

Breast milk offers the best chance for saving the infant. In a maternity the milk of some other patient known to be free of specific disease may be given until the mother's milk appears. If the baby is too small or too weak to be put directly to the breast, the milk should be expressed and fed to the baby either with a dropper or Breck feeder, preferably the latter; and as the amount needed at first is small the milk may be obtained just previous to feeding. When the mother's milk becomes available it should be expressed at least six times a day (1), emptying the breasts completely in order to maintain the milk supply. Later if the supply is abundant it may be expressed directly into the baby's mouth. If a wet nurse is employed her milk should be expressed two or three times a day, kept on ice and warmed before feeding. If either the dropper or Breck feeder prove impracticable, the baby may be fed by gavage through nose or mouth, using a No. 12 or No. 14 French catheter. Feeding from a dropper should not be prolonged as it induces fatigue; gavage may avoid fatigue, but if continued for too long a period may do harm by increasing risk of infection. The Breck feeder has the additional advantage of teaching the baby to suck. Breast milk, owing to its fat percentage, should at first be diluted at least one half and given in increasing quantities, until the caloric requirement is approached. It may be diluted with cow's milk, whey or barley water, and, if necessary, predigested (5). The use of sugar solution aids in combating low temperature.

Feeding the premature baby with artificial food is at best most unsatisfactory. All forms of milk preparations have been suggested to meet the requirements; milk dilutions, top milk mixtures, malt soup, condensed milk, buttermilk, etc., with or without carbohydrates.

In considering the quantity to be given, we must bear in mind the gastric capacity at various ages of fetal life; remembering that the walls of the stomach are elastic and, that the amount the baby can take is somewhat in excess of that usually set down as the gastric capacity for a given age.

In spite of the baby's need for a relatively large amount of nourishment, it must be watched for evidences of overfeeding and digestive disturbances and the formula varied accordingly.

DEGREE OF INCREASE

Smaller and slower increases in weight must be expected in those fed artificially. Fat percentage should be increased slowly. Sugar may be added to increase caloric value and supply heat and, the mixture may if necessary be peptonized; orange juice and cod liver oil should be given daily.

It has been estimated that the amount of fluid required daily by the premature infant is equal to one eighth to one fifth of its body weight (1). Plain boiled water should be given between feedings to supplement the fluid content of the milk in order to meet this requirement. The amount may be increased in the presence of fever and a high bassinet temperature. In most cases it is deemed advisable to keep the baby in the hospital until its weight approximates five pounds.

In the routine care of the premature baby where no pathologic condition exists we are chiefly concerned in the avoidance of the aspiration of the food, digestive disturbances, undernourishment, insufficient supply of water and infection.

DESIRE FOOR FOOD

Few premature infants show a normal desire for food and the more premature the baby the greater the difficulty in this respect.

While at first the baby may show a tendency to nurse, as it loses weight and becomes more weakened, it sleeps incessantly and refuses to swallow. Such cases require catheter feeding, stimulation, and fluids by mouth, rectum or skin. Physiological salt solution for one or two feedings is advisable in order to stimulate thirst (8). The intraperitoneal use of salt solution or glucose should be limited to small amounts (9).

The occurrence of vomiting must in most instances be regarded purely as a symptom. Vomiting the result of toxic or septic conditions will not here be considered. Little attention need be given to slight spitting up if the infant is doing well otherwise. Regurgitation frequently results because of the relatively vertical position of the stomach, over distention and handling. The approximate amount lost at each feeding should be noted, whether or not this amount is increasing and the presence of blood or bile.

If a baby is nursing directly from the breast, the number of nursing minutes may be lessened or the interval lengthened. In severe cases it may be necessary to express the breast milk, boil or predigest it.

If artificially fed the interval may be lengthened or the quantity lessened, or it may be necessary for a time to reduce the fat or sugar, or to use skimmed milk, boiled or predigested. The method of administration should be slow but not sufficiently prolonged to weary the baby. Should the vomiting be severe and persistent it may be necessary to procure a wet-nurse in an effort to save the baby's life.

It is obviously necessary to give all the nourishment both in quality and quantity that the baby's digestive capacity will permit in order to avoid the consequences of underfeeding.

Each baby must be considered individually. The quantity strength and interim of feeding should be prescribed each day, according to progress made and conditions present.

The baby should not receive its first feeding until a bowel evacuation has occurred. If necessary this may be accomplished by a small enema, or castor oil. Constipation occurs chiefly as the result of underfeeding or insufficient fluids and may be relieved by increasing the amount of water given and by strengthening the formula to a point slightly in excess of the digestive capacity of the baby. In addition a suppository may be held in the rectum, or the tip of a catheter oiled may be inserted at regular times each day.

Every baby should be considered a potential case of rickets, spasmophilia and anemia.

Without entering into a discussion of the etiology and symptomatology of rickets it is sufficient to say that there exists calcium deficiency in association

with a low percentage of inorganic phosphorus (1).

Associated with rickets in the premature baby, anemia frequently develops during the first three months of life (1). Likewise spasmophilia is found quite frequently in prematures, in the breast fed as well as in the artificially fed and apparently bear a distinct relationship to rickets and anemia (1). A diminution in the calcium salts in all probability is the most important factor in the development of this condition.

The prophylactic measures against all the above conditions should have been started early in intra-uterine life, by prenatal care of the mother.

After birth, preventive treatment should begin early, the following points being observed: Feeding breast milk if possible. Careful hygiene. Including fresh air and sunshine. Administration of orange juice and cod liver oil in increasing doses, or tri-calcium phosphate in emulsion in cod liver oil. Any other conditions which develop must be met as in the normal baby.

The existence of cleft palate, with or without harelip, complicates the feeding problem and diminishes the child's chances of living. We attempt to combat this by the use of a dropper or gavage if the baby is too weak to nurse, but if able to suck a special cleft palate nipple is availale which often solves the problem extremely well.

In estimating a baby's chances for life it becomes necessary to take into consideration many factors, chief among which are: Length of intra-uterine gestation, degree of development when expelled, weight, character of pregnancy and labor, presence of malformations and anomalies, transmitted parental conditions, maintenance of body temperature, initial loss of weight and complications such as: Injuries, anatomical defects, asphyxia, cyanosis, atelectasis, hemorrhagic diathesis, and infections (4).

Before the twenty-seventh week of fetal life there is slight chance of surviving (1). Under 1,500 gm. an infant has less than even chances for surviving. Between 1,500 or 2,000 gm. the chances are even, while over 2,000 gm. the chances are good, if there are no adverse complications.

An abrupt rise of temperature or failure to rise when the infant is placed in an incubator is an unfavorable sign (1).

An early birth from induced labor may be regarded more favorable than from spontaneous delivery.

The presence of syphilis, tuberculosis, nephritis, alcoholism, eclampsia and chronic heart disease, in the mother producing faulty nutrition in the fetus are all detrimental to ultimate survival (1).

Many infants with organs sufficiently developed to carry on the normal physiological requirements have overcome the handicap of prematurity by the end of the second or third year and compare favorably with full time children (1).

A certain number will, however, display characteristic skeletal changes with a tendency to the conditions previously described viz: rickets, anemia, spasmophilia.

The majority of premature infants born after the thirty-second week into a proper environment without birth injuries show normal mental development, except that they are somewhat slower in walking and talking, and with a tendency to exhibit temper and emotionalism (1).

Essential or Primary Hypotonia in Young Children*

JACOB SOBEL, M.D.

New York

In presenting the subject of muscle and joint hypotonia as it occurs in infants and young children, no attempt will be made to enter into a full discussion of all the diseases and disorders in which this condition is found. It is my purpose rather to direct attention to a class or group of children in whom there exists a primary or essential loss of muscle and joint tone, a muscular and joint atony, without the presence of any basic physical or mental disturbance and without any evident gross pathology in the muscles, joints, or bones. These children are brought to the physician by the anxious parent with the complaint that the child does not walk or stand, walks with difficulty or with unsteady gait, falls or trips readily, tires easily, limps, inclines the body to one side, is unable to sit up properly, or hold the head erect, or has curvature of the spine, or weak feet.

Perhaps it would be more interesting to record in their own words the chief complaint of the parents when these children are presented. They will tell you, "the ankles turn in," "all bones crack," "bends feet under him," "foot comes down," "walks crooked," "child trips all the time," "legs bend when walking," "back is round," "legs are weak," "don't use limbs hardly," "loose joints and walks funny," "falls easily," "don't stand," "don't walk," "can't keep head up," "don't sit right"—these or some similar and significant statements have been noted on my history cards under the heading of chief complaint. One parent stated, "when she sleeps her hip goes out of place when she turns over."

Upon physical examination the usual picture of this type of case is as follows:

The child as a rule is well nourished and free from

*Read at a meeting of The Harlem Medical Association, January 6, 1926.

Fig. 1.—Hypertension of the elbow, marked hypertension of the wrist and phalanges, genu recurvatum, pronated feet, distended abdomen.

Fig. 3.—Hyperextension of the wrists and phalanges.

Fig. 4.—Marked dorsiflexion of the ankles.

Fig. 6.—Subluxation of metacarpo-phalangeal articulations in the father.

any physical disease and mental or psychic abnormality. He either does not walk or stand, walks with a limp or an atypical waddle or in an unsteady manner. Upon sitting up his spine is kyphotic or scoliotic and admits of hyperextension with correction of the deformity. Examination of his extremities shows that his shoulders are more mobile than normal, there is hyperextension at the elbows, hyperelasticity of the wrist and fingers so much so that in some cases the fingers can be bent backwards almost to or to the wrist and the dorsum of the wrist to the extensor surface of the forearm. The thighs can be readily flexed upon the hip joint so that the toes touch the neck or the occiput in some cases. At times subluxation of the hip and shoulder can be demonstrated at will. Hyperextension, to the point of genu recurvatum, is seen at the knee while walking, or can be produced by manipulation, while by grasping the lower thigh the knee can be dangled, flail like, from side to side. There is a wide lateral give or play to the knees. At the ankle dorsiflexion will approximate the dorsum of the foot to the anterior tibial region. There is frequently a foot deformity in the form of a pes planus, as well as pronation, hypereversion and hyperinversion. There may be abdominal distention and constipation, in some cases very marked.

All the aforementioned manipulations can be carried out without pain or discomfort. There is no apparent atrophy or hypertrophy of the muscles, there are no sensory symptoms, no disturbances in deep reflexes, no abnormal electrical reactions, no apparent motor weakness, nothing to indicate a pathological change in the muscles themselves as a result of present or previous disease. There exists what appears to be a congenital defect in the muscle tonus without evident pathological basis. Coincident with this hypotonia of the muscles there exists a flaccidity of the ligaments and capsules around the joints and the combined result of an inherent loss of tone in muscles, ligaments and capsules gives the picture of joint hypotonia or flaccid joints.

Whether the atony of the muscles is primary and that of the ligaments and capsules secondary, whether the reverse is true, or whether they both occur at the same time due to congenital defect could not be determined by me from the history or examination of my cases.

While I have pictured here a class of cases in which the muscle and joint hypotonia is pronounced, I should like to emphasize that there exists a much larger group in which there is a moderate or mild degree of hypotonia, in which the hypotonia is less marked, the number of joints involved is less in number and the subjective symptoms and objective findings are less distinct. It is this latter group which comprises many instances of flat feet, round shoulders, and scoliosis in older children.

In speaking of myotonia congenita (Oppenheim's Disease) Holt brings out this point very forcibly as follows:

"Besides the marked form of disease, it is now recognized that myotonia may occur in all degrees of severity. In the mild form there may be only very great weakness and atony of the muscles. The ability to hold up the head or to walk may then be greatly delayed though the intelligence may be quite normal. These cases are often confounded with rickets. The milder forms of myotonia may be readily overlooked and may cause but little interference with function. Between these and the severe forms of the disease, there are seen all degrees of muscular weakness."

This circumstance finds its analogy in other conditions such as disorders of the thyroid gland in which we may have all the symptoms from a mild hypothyroidism to the typical myxedema or of a mild hyperthyroidism to the typical exophthalmic goitre. In fact the number of atypical cases outnumber those of the typical variety.

Hypotonia while well known to the orthopedist is frequently overlooked by the general practitioner; more than that—and herein lies the greater danger—it is frequently considered by him an evidence of some serious mental, osseous or neurological disease, with the result that needless and unnecessary alarm is excited in the minds of the parents.

For the want of a better term joint hypotonia refers to a type of case in which because of congenital or undiscoverable reasons there exists an abnormal mobility of several or all the joints of the body, without the existence of any essential changes or disease of the joints themselves. Except for a reference here and there in relation to certain diseases with which this condition is associated very little has been written on the subject. Since this condition often results in weakness or disability of locomotion, carriage, and posture it is natural that many of these cases should find their way to an orthopedic institution and it is from the Hospital for Joint Diseases

that the material which forms the subject of this paper has been gathered.

When in 1916 Dr. Harry Finkelstein published his paper he stated in his report that the case was "unique," "the first of its kind seen during ten years' service at the Hospital for Joint Diseases" and "that no similar instance had been cited in the literature."

Since that time, with greater attention directed to the condition, a relatively large number of cases, not all of great severity it is true, have been observed during the routine dispensary and hospital work at the Hospital for Joint Diseases.

These cases which I consider belong to the group of essential or primary hypotonia are generalized as a rule, affecting practically all the joints of the ex-

Fig. 2.—Pronounced hyperflexion of the hip joint.

tremities although in various degrees of severity, so that we find mild, moderate and severe cases, so mild as to be overlooked so severe as to be diagnosed as a grave disorder. The severity varies not only with different children but in different joints of a given case.

I should like in passing to refer to muscle tone in early infancy. During the first three or four months of life there exists in most normal infants a physiological hypertonicity of the muscles—the myotonia physiologica neonatorum of Hochsinger—as evidenced by the rigidity of the fingers, arms and legs and the maintenance of these parts in flexion a continuance as it were of the fetal position. Feer goes so far as to state that "frequently the neck muscles are involved so that the head is drawn backward in which case a meningitis or Little's Disease may be incorrectly suspected."

On the other hand in practically all new borns and during the early months of life the ankles can be dorsi flexed so that the dorsum touches the anterior surface of the legs, an apparent hypotonicity or myotonia. I say apparent because this, too, may be an expression of the fetal position in utero.

Later in infancy up to nine or ten months there is a normal amount of elasticity or give to the muscles and joints as witness the ease with which many infants make a pastime of putting their toes into the mouth.

But after allowing for physiological limits, we find that just as there exists the hypertonic infant, the infant described by Haas as one with general spasticity of the skeletal and visceral muscles, with psychic instability, insomnia, crying, vomiting, cold extremities, etc.—the myotonic, vagotonic or spasmophilic child—just so there exists the hypotonic or myotonic infant or child—placid, sluggish, inactive, easily tired, constipated, with hypermobility of the joints in varying degrees.

The hypertonic child is athletic in a sense in that it will grasp objects and raise its head easily or can be lifted almost *en masse* while his hypotonic brother will be delayed in grasping objects, sitting up, raising its head and walking.

Within the past three years during which I directed special attention to this subject, I have listed in my pediatric class at the Hospital for Joint Diseases forty-five cases of essential or primary muscle and joint hypotonia. Even at that as I reflect upon my material, I feel confident that many mild cases were overlooked. These cases grouped themselves as follows:

Age:	under 1		5
	1- 2		23
	2- 3		7
	3- 4		3
	4- 5		4
	5- 6		1
	8- 9		1
	10-11		1
Sex:	Male—22	Female—23	
Degrees:	Mild		7
	Moderate		21
	Severe		17
Other Members of Family Affected:	(Uncle		1
	(Father		1
	(Father		)
4	(Father's brother		1
	(Father's nephew		)
	(Mother		1

Enlarged Thymus:	Number Examined	Yes	No
	11	2	9
Diaphragm involved (Fluoroscopic Examination)	11	4	7

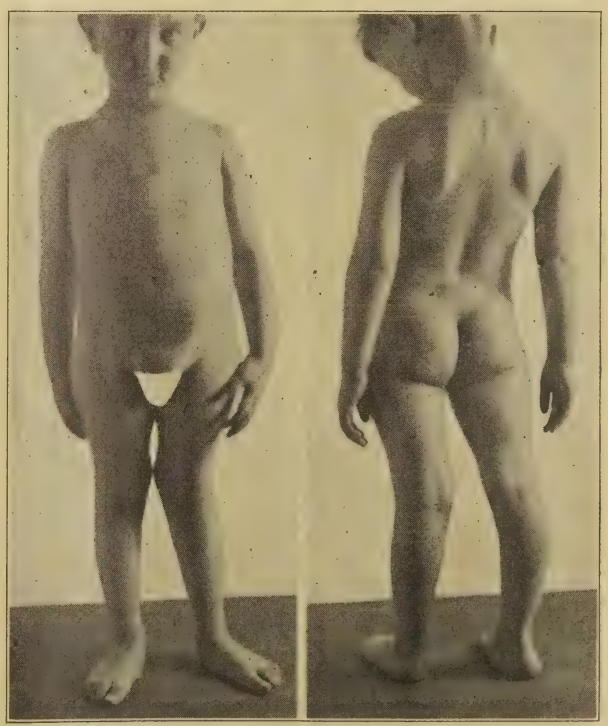

Fig. 5.—Hyperextension and lateral "give" of the knee joints.

I would not venture any opinion as to the frequency of this condition beyond the statement that it is more common than generally supposed. Nor would I base a statistical percentage of the frequency upon the number of cases recorded by me in the sum total of cases registered. The latter would neither be fair nor accurate because a very large number of

children applying at my pediatric class come for orthopedic or allied conditions.

I should like to call attention to an interesting phenomenon observed in one pronounced case of hypotonia (Hyman S., Registration No. 176793). This case was completely röntgenographed with the idea that possibly other structures than the joints were involved. The child was then fluoroscoped by Dr. Gustav Bucky, röntgenologist to the Hospital for Joint Diseases, and his report was as follows:

"There is no bone anomaly present. No demonstrable pathology on plates. However, fluoroscopic examination reveals what appears to be a paresis of the right diaphragm. The excursions about both diaphragms are irregular and disassociated the right moving down while the left moves up and conversely." We have here an abnormal disproportion in the height of the diaphragm and an incoordination of movement. Why should this condition exist? Given a diaphragm abnormally high on one side or the other the causes which come to mind are, 1, phrenic paralysis or paresis; 2, pleural thickening at the base of the lung causing paresis of the diaphragm (Krauss and Munk); 3, intraabdominal pressure (tumor, abscess, perihepatitis or perisplenitis).

None of these conditions obtained in this case. What then was the probable explanation?

Is it possible that the diaphragm partook of the general muscular atony and that just as there existed instability of locomotion, so in this case the diaphragm was atonic and coordinated imperfectly. Or is the explanation to be found in the fact that during expiration the abdominal muscles which play a rôle in this act and which in this case were atonic—the child was obstinately constipated—exerted uneven pressure or worked irregularly in the elevation of the diaphragm.

It is true that in the prototype of myopathies—Oppenheim's Disease—writers agree that the diaphragm, face and ocular muscles remain free. But admitting that in this disease there is no true diaphragmatic paralysis or paresis, does the diaphragm remain free in the sense that it acts incoordinately or imperfectly. To my knowledge no fluoroscopic examinations of the diaphragm have been made in Oppenheim's disease to establish this point.

With this case as a lead, fluoroscopic examinations were made in other cases by Dr. Bucky and Dr. Pomeranz, with the result that we established the fact that the aforementioned was not an isolated case. In addition to the case mentioned the diaphragm was fluoroscoped in ten other cases and in three cases some abnormality was found. The individual reports are as follows:

Harriet B., Registration No. 160500:

"Both diaphragms are at the same horizontal level. The general movements are equal and symmetrical on both sides, but careful observation shows that *every sixth to eighth inspiratory movement is somewhat irregular, the left diaphragm moving down before the right* and both returning to the horizontal level synchronously" (Pomeranz).

Richard O., Registration No. 177681:

"The movement of the both diaphragms appears somewhat diminished as far as the excursion is concerned. No difference of both sides" (Bucky).

Anna K., Registration No. 138758:

"The movements of both diaphragms are somewhat irregular. The radius of excursion of the right appears to be greater than the left, with some apparent delay in both rate and rhythm of the right diaphragm" (Pomeranz).

In all eleven cases were fluoroscoped and in four abnormal diaphragmatic function was disclosed.

An interesting observation in this connection was the fact that in some of the severe cases the action of the diaphragms was normal. Thus in the child whose photographs are presented and who was markedly hypotonic the report of Dr. Bucky was as follows:

Fluoroscopic examination: Negative. Speaking from the skeletal viewpoint joint stability and body equilibrium are maintained not only by capsular, ligamentous and cartilaginous attachments but also by the coordinated action of surrounding muscle groups. Any weakness of these muscles due to cerebral, spinal or peripheral nerve disease or other causes or to inherent myopathy will produce a weakness, laxity or undue mobility of the joints in question. In poliomyelitis, for example, with atrophy of surrounding muscle groups it is not infrequent to find subluxation of the hip, shoulder or other joints, a genu recurvatum or flail joints, albeit that the capsules, ligaments and articular surfaces are not involved; and so it appears to me that in joint hypotonia, atony of the muscle groups around the joints render them unstable and hypermobile, a mobility that is increased and exaggerated it is true by relaxation of ligaments and capsules. Finkelstein, however, states that "the only structures affected are the capsules and ligaments of the joints."

Abnormal mobility of the joints is found in varying degrees in many conditions which I have grouped under the following headings:

MUSCULAR AND JOINT HYPOTONIA

1. Congenital: Myatonia Congenita (Oppenheim's Disease)
2. Essential or Primary
   - Mild
   - Moderate
   - Severe
     - a Individual: One member of the family affected
     - b Familial: History of flail or double joints in parents, brothers, sisters or relatives
       Several members of same family affected
3. Metabolic: ..... Rickets
4. Neurological and Myopathic .....
   - Poliomyelitis
   - Multiple neuritis
   - Muscular atrophies and dystrophies
   - Friedreichs ataxia
5. Endocrinological
   - Thymic subinvolution
   - Cretinism
   - Mongolism?
   - Obesity
6. Cerebral .....
   - Imbecility
   - Idiocy
   - Amaurotic family idiocy
   - Cerebral malformation and maldevelopment
   - Cerebral flaccid paralysis
7. Functional .....Chorea
8. Nutritional .....
   - Disorders of nutrition
   - Wasting diseases
   - Chronic infection
   - Disuse of prolonged illness

CONGENITAL

1. *Oppenheim's disease.*—Variously called myotonia congenita, atonia musculorum congenita, myohypotonia, and amyotonia—of the typical kind is a congenital disease, observed in the early months of life; it presents a picture of extreme muscular weakness, seldom complete paralysis, incapacitates the child, affects the lower extremities to a greater degree than the upper without involvement of the diaphragm, facial and cranial nerves and muscles of deglutition. There is a loss of deep reflexes, joint hypotonia, quantitative diminution of electrical reaction without reaction of degeneration, but no sensory disturbance or disturbance of mentality. Sometimes there is hyperextension of the big toe. The disease is due to an embryonal defect of muscle development rather than to a degeneration. Improvement is possible but slow. Permanent cure has not been recorded. Death usually results from intercurrent respiratory disease.

PRIMARY OR ESSENTIAL

2. This includes the group of cases which form the subject of discussion. One or several members of the family may be affected and there may be a history of a similar condition in parents or relatives. Mild, moderate and severe cases are encountered. Progress is good and recovery takes place in later childhood or adult life. Some cases carry the condition throughout their life time.

METABOLIC

3. Rickets is representative of this type of hypotonia. While the osseous changes are characteristic the condition is far from a disease of the bones alone and involves the muscles, ligaments, capsules, mucous membrane and nervous system. In fact, the muscular symptoms are just as characteristic, as common and as constant as the bone changes and often appear before marked changes in the bones are evident. In truth Moore states that abnormal lateral mobility of the knee joint is often the first clinical sign of rickets demonstrable in the legs; abnormal knee mobility is of value in the early diagnosis of rickets and furnishes a means of measuring improvement during treatment.

MUSCLE CHANGES

In other words in rickets we have a joint hypotonia due not only to changes in ligaments and capsules but to changes in the muscles themselves. Still says, "Nor is it only the bones which yield to mechanical influences in rickets; the ligaments are unduly soft and lax, as can be seen in some rickety children in the extraordinary contortions of which their joints are capable; some rickety children can easily put their toes behind their ears and the knee joint can be felt to be abnormally lax. In part the yielding of the ligaments is, no doubt, due to the feebleness and laxity of the muscles which afford but little support to the joints; but it is probably due also to some change at present unknown in the ligaments themselves. Consequently any stress upon the joints is likely to result in deformity in addition to that resulting from bent or fractured bones."

ATONY

I stress the atony of the muscles in rickets as part of the joint hypotonia found in this disease, because I believe that in Essential or Primary Joint Hypotonia the lack of muscular tone plays a predominant part.

ENDOCRINOLOGICAL

4. *Thymic subinvolution.*—In addition to the other characteristics of this type of child Timme says, "The joint elements are not firmly bound together so that they are readily hyperextended even to the point of subluxation in such joints as the mandibular, the shoulder and the metacarpal. The sacro iliac and tarsal ligaments are likewise lax. The extremities hence give the appearance of flails and the body may frequently be contorted in the most grotesque manner."

We have had eleven cases of essential hypotonia examined for enlarged thymus and in two only have we found any suspicion of such, the reports reading:

Raphael, P., Registration No. 153026:

"Enlarged upper mediastinal shadow. Advise therapeutic test."

Victor, R., Registration No. 150839:

"Upper mediastinal shadow, probable thymus, suggest therapeutic test."

Cretinism.—In the typical case there is not only retarded physical and mental development, skin and hair changes, hypertrophied tongue, low temperature, low metabolic rate but also a hypotonic muscular structure resulting in delayed walking, flat feet, pot belly and constipation.

Mongolism.—The musculature is poorly developed and flaccid, the ligaments are relaxed admitting of distortions of the joints. All mongols are flat footed. Mongolism is an anthropological rather than an endocrinological condition and is listed under the latter heading merely as a matter of convenience.

Obesity.—This is often associated with weak and flabby muscular structures and resultant hypotonia.

NEUROLOGICAL

5. The hypotonia in this class of cases is of course part of the general picture of the diseases noted and any discussion of them would be foreign to the subject.

CEREBRAL

6. These are mentioned merely to call attention to hypotonia as part of the symptom complex.

CHOREA

7. In chorea there exists not only incoordination but often a weakness or hypotonia of muscles so great at times as to lead to a suspicion of paralysis.

NUTRITIONAL

8. The diseases noted in the table may all lead to hypotonicity of a degree dependent upon the duration and extent of the disease.

I have touched upon some of the conditions in which muscle and joint hypotonia is found merely to show how different the picture is from the cases of primary or essential hypotonia under discussion.

Essential or primary muscle and joint hypotonia differs from the hypotonia found as part of the other diseases mentioned, in that there exists no evident or apparent physical, mental, neurological, osseous, joint, or other factors, that practically all the joints are involved rather than special ones, that the condition is sometimes familial, that the muscles are appar-

ently normal to sight and touch and measurement, that there is no apparent motor weakness or sensory disturbance, no change in electrical reaction, no change in tendon reflexes, and finally that in the majority of cases improvement or recovery takes place during later childhood or in adult life.

THE PARENTS

Few considerations cause more alarm to parents than the fact that a child of two or three years, apparently normal in other respects, does not walk or stand or walks imperfectly. Sombre thoughts cross their minds and only too frequently the minds of many practitioners who have been taught to look with suspicion upon such cases as due to either rickets or mental retardation.

Holt says, "The physician is often consulted because of backward muscular development, most frequently because the child is late in walking. General malnutrition or any severe or prolonged illness may postpone for several months this or any of the other functions mentioned. When there is no such explanation of the backwardness, a child who does not hold up his head, sit alone, or make efforts to stand or walk at the proper time should be submitted to a careful examination for mental deficiency or cerebral or spinal paralysis but especially for rickets, which is the most frequent explanation of the symptoms." And Still says, "The age of learning to walk varies very considerably in health, but I think it may be said that if a child is free from rickets and other physical disease and makes no attempt to walk at the age of eighteen months, mental deficiency is at least probable."

No one can contradict these authoritive statements, and yet I venture to say that where a physician is consulted because of backward muscular development or because of late walking or standing he will find a hypotonia more frequently than mental deficiency, cerebral or spinal paralysis, and often enough a primary hypotonia rather than rickets.

TIME OF WALKING

While on the subject of walking, let me remind you that there exists the widest difference among different families, regarding the time at which children first walked. In some we find that the children walked at ten or eleven months, in others at seventeen or eighteen months or later. Both are classified as within normal limits. In going into the family history of some of my cases of hypotonia, I found that the older children of the family did not walk "until late," strong presumptive evidence of a similar hypotonia in them as well as in the case at hand.

EASE OF DIAGNOSIS

Like so many other diseases in medicine which admit of a ready diagnosis, if one only thinks of them—pyelitis, diabetes, scurvy—muscle and joint hypotonia will be found more frequently by those who think of and look for it. Given a child of from eighteen months to three years whose appearance is normal and whose mother complains of its delayed or difficult walking, standing or sitting or similar symptoms the first thought in the mind of the examiner should be hypotonia.

That such is not the case is attested to by the fact that many of the cases referred to my class at the Hospital for Joint Diseases came with a diagnosis of rickets, paralysis, mental deficiency, nervousness, or "nothing"—the latter a favorite diagnosis to cover ignorance or satisfy the parent.

CONSTITUTIONAL BEARING

It requires no great imagination to realize what such statements by the physician mean to the mental and emotional status of the parents.

The existence of hypotonia is important not only from the locomotive but from the general constitutional viewpoint. A hypotonia which involves the muscles of the chest renders the patient not only more susceptible to respiratory conditions, but minimizes the chances for recovery in the event of such occurrence. A hypotonicity of the abdominal muscles or intestinal tract makes atonic constipation with its attendant train of symptoms of fermentation and toxemia, a factor of great importance in the care of children. These two examples suffice to explain why so many mongols frequently suffer from and only too often succumb to intercurrent respiratory disease and why rickets is so frequently accompanied by constipation, abdominal distension and pot belly. And in essential hypotonia when not only the extremities but the diaphragms, intercostals, or abdominal muscles are involved, the dangers above mentioned should be kept in mind.

PROGNOSIS

Finally, a few words as to prognosis and treatments. Most of these cases improve or recover, although it may take many years. Those that I have been able to follow showed some improvement under massage, educational exercises, warm baths, fresh air, sunlight, proper hygiene, codliver oil, syrup of iodide of iron, regulated and balanced diet and the use of mechanical appliances. The improvement of these cases with advancing years leads one to the thought that the condition may be due to disturbed metabolism and that with changed and adjusted environment and diet, a betterment of metabolism and improvement of muscular tone follows.

Dietrich writes that, "Herodotus 431 B. C. mentioned the sun bath and recommends it for restoring muscular tone."

I have had only a limited opportunity of using actinotherapy in this condition—some six cases in all—and it has appeared to me that an improvement in the general well being and in the muscle tonus has taken place. I feel that its application by increasing cellular function and activity, enhancing metabolism, and increasing hemoglobin, erythrocytes, phosphorus, calcium and iron, offers advantages for these children and that it should be used wherever available.

I desire to thank Dr. Henry W. Frauenthal, physician and surgeon-in-chief of the Hospital for Joint Diseases, for the opportunity afforded to study and present this material.

LEPRA ARABUM OR ELEPHANTIASIS ARABUM

This disease is scarcely known in this country nor is it seen in these latter ages. Avicenna of the eleventh century describes it as follows:

A disease corrupting the complexion, form and figure of the members proceeding from corrupt bile diffused through the body with a hot and dry temperament of the bowels, spoiling their sanguinification and generating this peculiar and specific venenate quality. The propagation of this disease is: a, heredity; b, contact by common conversation or venereal copulation, and c, spontaneously from a proper vice generated or promoted by bad air and diet.

Paulus Aegineta terms it "universal cancer."

Gregory Hostius says: "It is a foul, contagious disease characterized by its cancerous cachexia of the whole habit arising by some fault of the liver and spleen from atrabilious adust humors."

Symptoms: Hair of head, beard, eyebrows and eyelids shed; the look is fierce, ears acuminated, lips thick, nostrils swell outward, face appears full of unequal tubercles of a livid color, veins of the tongue are varicose, the skin is greasy so that water slides off and will not tarry on it, little knobs appear thereunder. The skin may seem like unto that of a deplumed goose. It may be chopped and furrowed like the hide of the elephant or crusted with dry scab and impetiginous eruptions.

Howard F. Damon's description: "It is a disease attacking the lower extremities, producing an enormous, unwieldy, misshapen extremity which rests on the tumefied foot and is burying it beneath the impending mass of swollen and indurated tissue. This form of elephantiasis may attack the scrotum, increasing it in size to such extent that it reaches the knees and may equal in weight that of the whole body. The labia majora in women when affected may be the size of a child's head. The breast may also be affected."

Rasmussen (3) describes its symptoms as follows: first stage, chills followed by high fever, headache, restlessness and an inflammatory process similar to erysipelas extending from the part first attacked. There is marked redness and a deep, firm, edematous swelling. The lymphatic vessels are early attacked and resemble hard cords. The lymphatic glands are swollen and suppurate. The fever lasts one or two days and terminates in copious perspiration. The swelling subsides, pain disappears and the patient gets apparently better. After several months a similar attack occurs. This attack may also disappear. After a third attack the disease passes into its second stage. The swelling becomes stationary. This being slowly developed into the well known deformity termed "elephant leg." There is also an apyrexial form without fever, and but slight pain. Yet the part, nevertheless, increases in size and hardness.

The inflammatory process is taking place in the lymphatic glands and vessels. The red tender bands, the enlarged suppurative glands, the enormous tumefaction of the parts, their hardness which is so different from ordinary edema, and the occasional occurrence of attacks of erysipelas either at the outset or during the progress clearly point to its origin or seat in these organs.

A proper consideration of the representations outlined above of the disease by the different writers perplexes and confuses the mind of the careful reader. Compare the description of lepra arabum by Avicenna with that outlined by Damon or the symptoms described by Hostius with those represented by Rasmussen.

The difference is so striking that one cannot help wondering whether or not they are dealing with one and the same disease. Indeed, it would be a very difficult problem to solve if the descriptions would not bear the same designation. The most conspicuous differentiating point in their outline of the disease is the fact that Hostius describes it as a constitutional affection and dwells chiefly upon the involvement of the hair, skin and almost every organ of the face without even mentioning the lower extremities, while Rasmussen and Damon state that lepra Arabum is an affection of the lower extremities and do not mention any involvement of other organs. How can it be explained?

This seemingly puzzling question can be readily explained by the theory outlined in the introduction of this paper. The fact that the older writers described the disease in the eleventh century and the younger in the nineteenth is enough to explain the difference in the descriptions. During the former period the disease was at its highest point of development. The virus was extremely virulent and capable of producing constitutional symptoms while at the latter period it reached its stage of decline and is, therefore, becoming more or less localized.

LEPROSY OF THE GREEKS OR ELEPHANTIASIS GRÆCORUM

Hippocrates and Galen describe it as an unequal discoloration of the upper part of the skin characterized by white leprous spots sprinkled over the skin, arising from a salt phlegm or other vitiated juices thrown forth of the blood and lodged in the outward parts.

Pliny says, "the disease came to Italy at the time of Pompey, the Great. It started on the face in spots like a small lentil. Soon after the whole body was invaded with tubercules of various sizes and colors, crusted over with a dry and rugged scab which at length turned black and ate the flesh to the very bones."

He remarked that when an Egyptian King was afflicted with this disease, he would order a bath of human blood as a medicine. Very interesting is one of the remedies recommended by Galen and others of his time. He advises the use of the flesh of the viper and believes that this is the best antidote. He relates that wine in which a dead viper was found, was given to a leper with the intention of poisoning him and free him from a torturous life, resulted in a perfect cure. Poterius recites a case of a Dominican Father who was cured by being fed upon the flesh of the viper. It was administered to him in a dry powdered form mixed with sugar and cinnamon, sprinkled among other food. One hundred and fifty vipers were thus used up. Damon's extensive description of this disease does not differ much from those outlined in any modern standard textbook on Dermatology. It is, therefore, unnecessary to repeat it and burden the mind of the reader of this paper.

The bacillus of leprosy was born and had its period of development in ancient Egypt. At the time of

Hippocrates and Galen it traveled to India, China, Australia and the northernmost parts of Europe. It reached its highest point of activity during the medieval period, when it invaded almost every country of the world. Its contagious power must have been very high at that time. At the beginning of the modern period the bacillus became too old to travel and has, therefore, decided to settle down in Norway under the assumed name of "spidalskhed." Its contagiousness at present is not very marked and, following the great law of Nature, it is gradually declining.

The Law of the Creator is compact, firm and unyielding. The astronomer possesses the power of observation, calculation, measuring, and even weighing the sidereal bodies, but has no influence whatever upon their movements. The geologist, botanist and zoologist can solve problems, enter into the secrets of Nature and explain scientifically every puzzling occurrence, but have no power of altering the perpetual course of action.

The physician, however, is the nearest to God. By means of his physical, chemical, electrical and therapeutical agents he can change the course of a disease. He is the commander in chief of such a faithful army of soldiers as hygiene, antiseptics, germicidals, serum therapy, vaccine therapy, hydrotherapy, electrotherapy, heliotherapy, röntgen rays, and radium. With the help of these soldiers he can prevent the evolution of diseases and hasten their period of decline for the benefit of humanity at large.

Contributors to the Science of Medicine

William Heberden

The lives of three physicians, Sydenham, Hans Sloane and Heberden, may be said to completely bridge over the uncertain period between old empiricism and medical science. Heberden was the last of this trinity. The lives and careers of Sydenham and Hans Sloane have been sketched. William Heberden, the son of Richard Heberden, was born in London in the year 1710. In 1724 he entered at St. John's College, Cambridge, took the degree of B.A. in 1728, and of M.A. in 1732. He obtained a fellowship in 1730 and then took up the study of medicine. Having taken the degree of M.D. he practised his profession in the university for ten years. He gave an annual course of lectures on materia medica and the specimens collected by him were, in 1750, presented to his college. A few extracts from these lectures may interest our readers as showing the state of knowledge of materia medica of the day and the mode in which the physicians of that period wrote.

Antimony.—Diascorides mentions it had a vogue in physic, but it was not of long date, because it is very dangerous. In about the twelfth age, Basilius Valentinus, a certain monk, published a book which was entitled *Currus Antimonii Triumphalis*, wherein he undertakes to affirm that it was a remedy against all sorts of diseases. Three hundred years after, Paracelsus brought it into vogue; but then in the year 1566 the use of it was condemned by Act of Parliament; and accordingly, one Besnier, a physician—transgressing it—was excluded from the faculty. In the year 1637 antimony was again received by public authority, among the purging medicines; and in 1650 the Act made in 1566 was repealed. In 1657 the faculty caused it to be inserted in their Antidotarium, printed that year herein following the opinion of Mathiolus; and on March 29, 1668, gave it the sanction of public authority, by which graduates were permitted to use it; but with a prohibition to all others, unless by their advice. Among the ancients antimony was used to dye the supercilia, or eyebrows, black; and accordingly we read in scripture, that the wicked Queen Jezebel in order to charm the King, her husband, painted her eyes (by which Heberden supposes is only meant the eyebrows with antimony) and the women who used that practice were also reproved by the prophets; and from thence it was that this mineral got the name of yovaikelov, while some Greek authors mention it thus, *στιμματογραφ*; because it seems to dilate the eyes and make them appear fuller.

It acquired the name of antimony in the opinion of some from the aforesaid Valentine, who, in his search after the Philosopher's Stone, was wont to make much use of it for the more readily fluxing his metals; and throwing a parcel of it to some swine, he observed that they were violently purged by it after they had eaten it, but afterwards grow the fatter upon it, which made him harbour the opinion that the same sort of cathartick exhibited to those of his own fraternity might do them much service; but his experiment succeeded so ill that everyone who took of it died. This, therefore, was the reason it was called antimony, as being destructive to the monks.

In these days when the herbal remedies are little used in comparison with the ancient practice of medicine, but when they seem to be coming into favor

again it is instructive to hear what Heberden has to say on the matter.

Vegetables.—There was a great dispute among the ancients, whether vegetables or fossils were best in physic. The vegetables were more used by the Galenists than Paracelsians. It is idle for us to regard these disputes, for there are extreme good medicines made from them both. Indeed, it was the general opinion formerly, that physicians ought to be chiefly skilled in the knowledge of vegetables; and Virgil hints at it when he says:

"'Scire potestates herbarum Medendi,' though there is little reason to think that vegetables are so universally good in physic, and numbers of them might be laid aside, if it was not for the two grand ingredients Mithridate and Theriaca. Our use of vegetables is greatly owing to our fondness for foreign vegetables, and those which our forefathers used; though the botanists at present are very little regarded by the physicians."

It will be noticed that these paragraphs are marked by numerous classical quotations. Heberden did not confine himself to writers on medicine, Homer, Plantus, Plutarch, Vitruvius, Horace, Cicero, Lucretius, Ovid, Persius, Caluttus, Juvenal and Pliny, all illustrate his discourses.

The physicians of the period in which Dr. Heberden was a leading light, generally possessed a good knowledge of Latin, and some of them of Greek as well. Heberden was an excellent example of the best type of physician of his time. In 1746 he was elected a Fellow of the Royal College of Physicians, and two years later he commenced practice in London. In 1749 he was made a Fellow of the Royal Society and initiated Philosophical Transactions to which he contributed four papers. In 1778 he was elected an Honorary Member of the Royal Society of Medicine, Paris.

It was customary to publish notices of the deceased honorary members of this society in its Transactions, and Dr. Heberden had drawn up an account of himself leaving blanks for the day, month and year of his decease. Here is the account:

"Dr. Heberden died in Pall Mall, on May 17, 1801, at which time he had reached his ninety-first year, and was the senior fellow of the College of Physicians. The serenity of his mind at this trying hour is shown by the recorded fact, that within forty-eight hours of his decease, he repeated a sentence from an ancient Roman author, signifying that 'Death is kinder to none than those to whom it comes uninvoked.' He admirably illustrated the truth of an observation made by the late Dr. Knox, that 'Religion is able of itself most effectually to dissipate the clouds, and to diffuse a sunshine on the evening of life.'"

His resolution to retire seems to have been formed in consequence of the impairment of the faculties of the celebrated Dr. Mead, whom he met in consultation when Dr. Mead was in this condition. It is stated that Heberden, then determined that if he ever lived to the same age, seventy-eight, he would give up practice. He retired in 1782 at the age of seventy-two when his faculties were perfect. His earliest published work was a little pamphlet entitled *An Essay on Mithridatium and Theriaca.* It appeared in 1745. The famous antidote to the baneful effects of poisons said to have been possessed by Mithridates, King of Pontus, is here shown to have been composed of the most simple ingredients: namely, twenty leaves of rue, one grain of salt, two nuts and two dried figs. Dr. Heberden states, that the ancients were only acquainted with three kinds of poisons, hemlock, aconite, and that of venomous beasts, and to these they knew no antidotes.

Dr. Heberden ridiculed the accounts of miraculous stories regarding poisonous substances generally emanating from Italy. Such as the concealing of poisons under the stone of a seal or ring, as reported by Theophrastus, or by vapors arising from perfumed gloves or letters. Many modes of poisoning are mentioned by Heberden, as having been practised by the Italians, among others that of poisoning clothes. However, as Heberden points out that these practices were not confined to Italy but were practised in England, Queen Elizabeth lived in constant dread of being taken off in this way. The poet Rogers alludes to the poisoners of the sixteenth century in the following lines:

> "Misnamed to lull alarm,
> In every palace was the laboratory
> Where he within brewed poisons swift and slow
> That scattered terror 'till all things seemed poisonous,
> And brave men trembled if a hand held out
> A nosegay or a letter; while the great
> Drank only from the Venice-glass, that broke,
> That shivered, scattering round it as in scorn,
> If aught malignant, aught of thine was there,
> Cruel Tophana."

Dr. Heberden was a somewhat voluminous writer; among his contributions to medical literature were the *Epidemical Cold, in June and July, 1767.* Of course, the epidemical cold was an outbreak of influenza.

Hectic Fever—Dr. Heberden was the first writer to expound John Hunter's views that fever was the effect of repeated formations of matter and not of its absorption. *Remarks on the Pulse, Diseases of the Liver, Of the Nettlerash, Angina Pectoris.*

The most important of his works was the *Commentani de Morborum Historia et Curatione.* This book was published in Latin and in English. He had long been in the habit of making notes at the bedside of his patients and every month he used to select and copy out under the correct titles of the diseases whatever he thought particularly worthy of record. In the year 1782 he made a digest of this register into the form of a volume of *Commentaries on the History and Cure of Diseases.*

Heberden was a great physician and his greatness lay, not in original views but in sifting the true from the false, separating the genuine from the doubtful and placing the truth on a firm basis. Cullen often said that there were more false facts in medicine than false theories. Heberden acted on this principle and proceeded with so great care aided by conspicuous ability and remarkable intuition, that his narrative of the symptoms of disease and of the effects of remedies as they presented themselves to his judicial intellect and to his wide experience affords a clear picture of deductions to be drawn from the observations of such men as Sydenham and the Hunters.

So highly did Soemmering consider Heberden's Commentaries that he republished them in Germany. Heberden was a friend and one of the medical attendants of Samuel Johnson.

Editorial Articles

NATIONAL HEALTH

There is plenty of scope for those who practise remedial, curative or preventive treatment. There seems to exist a fear that if prevention of disease is carried to its legitimate limits that the medical man will be restricted in his sphere of practice. In short, that the enlargement of the scope of preventive medicine will prejudice the position of the practitioner. The fear to a large extent is ill founded, and even if the expansion of preventive measures does alter the existing methods of practice, it behooves the members of the medical profession to adopt themselves to the changed conditions, conditions which have inevitably come to stay. As a sign of the times, the publication of a revised edition of an outline of the Practice of Preventive Medicine, written by Sir George Newman, Chief Medical Adviser to the British Ministry of Health, is peculiarly fitting.

The guiding feature and essence of the arguments contained in this memorandum, couched in eloquent and striking language, is that prevention rather than cure should be the goal to be aimed at. That the first duty of medicine is not to cure disease but to prevent. While much progress has been made in this direction, the writer takes upon himself to point out how much greater success can be achieved in the future, and accordingly a national policy is set out in logical sequence. It is the belief of Sir George Newman that heredity and race exert a greater influence upon health than environment.

He gives expression to this belief in the following emphatic words: "If we permit ourselves to favor and provide for the unguided propagation of a population of poor physique or of persons marked from birth with the stigmata of alcohol, venereal disease, or mental deficiency, we shall sooner or later discover that we are building on false foundations." It is pointed out, for example, that feebleminded women are, on the whole, more prolific than normal parents, with the result that this racial malady is being continually passed on.

It is needless to say that the situation, in this respect, is the same in this country and in all other countries. The least fit physically and mentally are reproduced in greatly larger numbers than the fitter, with the result that the tainted in mind and body bid fair to swamp the hale and sane.

In the well to do classes, in this country as in Great Britain, the birth rate has greatly declined. On the other hand, in the poorer—it may be said in the poorest—classes it continues very high; for instance, miners in England have double the birth rate of doctors.

This excessive multiplication of children under conditions which are generally, perhaps, unfavorable to a healthy life is not only a loss to national health but is a menace to individual health, that is, to the health of women who have excessive families. Many women are made invalids for life or lose a large part of their economic value. As a matter of fact, in Great Britain, and in other countries to a less extent, population is increasing at the wrong end. The people who can afford to maintain their offspring and to rear them under healthy conditions are having progressively fewer children, partly because of the increased cost of living, partly from selfishness, and an increasing love of comfort and luxury, and also on account of the fact that parents desire for their children the best that can be had in the way of education and training, so that they may be well equipped for the battle of life. On the other hand, people who are living in crowded slums under unhealthy conditions continue to have multitudes of children, many of whom live to be a burden on and a menace to the nation rather than an asset.

It should be borne in mind that the future of preventive medicine lies largely in domestic and personal hygiene. Public sanitation has abolished in civilized countries large epidemics. The object now is to fight the chronic diseases as rheumatism, which provides a holocaust of victims in deaths and cripples every year. The first step in this campaign is the abolition of slums and the provision of good houses. The next step is the education of the masses, including the well to do, in the principles and practice of personal hygiene, not forgetting that of diet. Personal and domestic hygiene carried out efficiently will result in a lessening of the chronic diseases, and in course of time in the doing away with some. In this campaign the doctor will be the most prominent figure as he must be the educator.

ODONTECTOMIES

Of all minor operations none seems more gruesome and apparently few are, in the present day, more dangerous than that of tooth extraction. Time was when people had a tooth pulled, and with great relief, but this event seems likely soon to be dignified with the term odontectomy, so formal and fearsome it has become.

Dr. George Blumer has called attention, in the

Boston Medical and Surgical Journal, to the "tragedies of tooth extraction," and has given account of some fatal cases which have recently come to his knowledge. Besides these fatal cases there have come to our personal knowledge instances of local infection and abscess formation following this operation. In two of the fatal cases described by Blumer the patients were apparently healthy up to the time of extraction of an uninfected tooth in one and the drainage of a root abscess in the other. The fatalities were, evidently, due to general infection and the process was rapid. The other two cases reported were of persons not in the best of health and several teeth were removed evidently in the hope of improving the general condition. The extractions resulted in nonfebrile processes of an infectious nature affecting the liver and the kidneys.

It is the practice nowadays of dentists to do considerable curetting about the sockets from which the teeth have been removed, and this would seem to increase the possibility of the development of abscesses in the neighborhood as well as of local infection elsewhere or of general toxemia. Sufficient trauma is occasioned by the removal of the tooth without adding insult to injury by means of the curette, especially since there is ample opening for discharge of infected material from the jaw.

The removal of teeth should not be recommended without the most careful consideration of the general condition of the patient and as to whether he is likely to be benefited—in other words, whether the cure thus conceived may not prove worse than the condition of which he complains.

Dr. A. E. Taussig speaking before the St. Louis Dental Society on Focal Infection from the Teeth and Internal Medicine said: "If I were to sum up my feeling about this entire problem, it would be somewhat as follows: 1, Patients with apical abscesses and systemic disease apparently due to focal infection should not have any useful, even though infected, teeth drawn until other foci, especially in tonsils, sinuses and prostate, have been investigated and eradicated. 2, Even where it seems entirely probable that the focal infection is in the teeth, the gravity of the systemic infection must be weighed against the handicap involved in the loss of useful teeth. I have repeatedly seen patients made utterly miserable on account of the loss of chewing power and the inability to have dentures in their mouths, when their condition had been entirely bearable before the teeth had been removed. 3, In cases in which there is no systemic disease, or only a trifling one, that can definitely be ascribed to focal infection, the problem becomes a purely dental one. In such patients, useful teeth, even though pulpless or evidently infected, should not be sacrificed merely to prevent possible later systemic disease. I have seen this done repeatedly and with deplorable results."

Strangely enough he believes that "pyorrhea, caries and the like, however important to the dentist, have no bearing on systemic infection." This is quite a different tune from that we have been hearing on this subject.

ANAPHYLACTIC ASTHMA

A certain similarity between the accidents of anaphylactic shock and the asthmatic paroxysm has for some time past attracted attention. There is the same sudden onset and violent dyspnea as in asthma with a slow respiration and dilatation of the thorax with forced inspiration. The bronchial and eosinophile cells described by Besançon and de Jong in the pearly sputum of asthma have also been found by Schlecht and Schwenker in animals dead in a state of anaphylactic shock.

Etiologically, essential asthma develops—like hay fever—from the presence of microspores and animal or vegetable dust. The proximity of a stable or a field are enough to render a place unhealthy for an asthmatic subject. The quantity of these substances sufficient to produce an asthmatic paroxysm may be merely a few aberrant grains. These pollens and dusts are albuminoids, all substances particularly qualified to produce the anaphylactic attack.

Urticaria—whose anaphylactic origin is distinctly demonstrated—is frequently encountered in asthma during the paroxysms or their intervals. In the asthmatic, the specific substance may be introduced by either the respiratory or digestive tracts. An error in diet is often quite enough for provoking an attack.

Now, it is common knowledge that anaphylaxis can be induced by both these tracts. Infection likewise plays an important part because out of a total of 775 cases collected by Percepied, in 190 the first paroxysm succeeded an infection. Occasionally asthma may be hereditary and we know that the anaphylactic state can be transmitted from the mother to the fetus.

Finally, it has been noticed that certain drugs, such as ataspine, calcium chloride and adrenalin exercise a remarkable action both on the asthma and anaphylactic accidents.

In spite of these similarities, the proof of the anaphylactic origin of essential asthma was wanting until 1914, when Widal and his coworkers demonstrated the fact. They observed the case of a sheep dealer who, although having lived among these animals since the age of twelve, only developed his first paroxysm at the age of forty-seven years. At first the attacks occurred only in summer but afterwards continued throughout the year.

By placing this man in an atmosphere filled with the odor of sheep experimental attacks were produced, each one being preceded by a true hematic shock, characterized by a marked leucopenea, a fall in the blood pressure, an increase of the blood coagubility and a decrease of the refractometric index of the blood serum, all these being precursory phenomena met with by these observers in other anaphylactic reactions, such as paroxystical hematuria or urticaria.

The vasculosanguineous attack, or hemoclastic shock, which clinically characterizes all these states, was present in this case with all its component elements so that the anaphylactic origin of the asthma was patent, but it remained to determine the nature and variety of substances to which the subject was sensibilized and this is one of the most complex problems of the process. However, certain results have been obtained by subcutaneous injections of certain albumoids and by the intradermic, ophthalmic and cutireactions.

Landouzy regarded asthma as due to larvate tuberculosis, supposing that the paroxysms were anaphylactic phenomena due to a release of tuberculine, and Heckel affirms that twenty-five per cent. of asthmatic patients are tuberculous, but he very justly remarks that it is evident that—given the frequency of tuberculosis—if all the various manifestations of this disease were sufficient to produce asthma, nearly all human beings would be asthmatic.

In asthma, the anaphylactizing causes are both varied and numerous. Besides the possible action of the bacillus of tuberculosis, pulmonary actions must be added, namely: 1, *mechanical* (compression, inflammatory cicatrices, lymphnodes, etc.); 2, reflex; 3, anaphylactic from ordinary bacteria; 4, alimentary anaphylactics (especially milk, eggs and bread); 5, cutaneous animal protein anaphylactics (horse, sheep, cat, birds, furs, woollens), and lastly, that determined by pollen which plays such an important part in hay fever, and certain dusts. It is the multiplicity of these factors, several of which may act in a single case, that makes specific antianaphylactic treatment of problematical efficiency. The elimination of one or several of these factors is not always sufficient to produce a cure of the asthma as long as other causes still exist.

Hence tuberculosis cannot alone be incriminated as the only cause of asthma, although it is frequently met with in this disease.

To Walker especially is due the credit of demonstrating the various albumins to which asthmatics are sensibilized. He employed the cutireaction with various albuminoid solutions and found the fifty-five per cent. of asthmatic subjects are sensitive to one protein while some are sensitive to several. A curious fact is that these subjects are sensitive above all to albuminoids derived from the horse, but others react to other animal or vegetable albumins, particularly to proteins derived from wheat and vegetable meals, pollen, eggs, and less commonly those from milk, meat, potatoes, woollen and feathers. Numerous asthmatics have been sensibilized by bacterial products extracted from sputum, the intestine or alveodental suppuration.

We would remark that the question of essential asthma is not entirely dependent upon anaphylaxis. Widal, Abrami and Brissaud have shown that the phenomena of *protein shock* may follow a first rather strong injection of some heterogeneous albumin or even a crystalloid substance. Cold and fatigue may produce changes in the colloidal complexes and by themselves produce an hemoclastic or colloidoclastic shock. Menstruation, pregnancy, lactation, and the menopause possess an undeniable influence on account of the humoral changes arising during these phases of female genital life.

We know that asthmatics are hypervagotonic subjects. Lion and Catuala found a positive oculocardiac reflex present in all their cases, a phenomenon denoting hypertonia of the pneumogastric. There is, evidently, a special susceptibility—constitutional or acquired—of the cells of the bulbar physiological centre of the inspiratory muscles, so that any shock acting on the origin of the vagus exalts its bronchospasmogenous function.

Heckel points out that many asthmatics present disturbances of the great sympathetic, so that it does not seem possible to regard asthma solely as a functional disturbance of the vagus, but rather of the vagosympathetic system.

ACCESSORIES FOR HEALTH

In every sickroom, in every hospital ward, there is introduced an agent for good which is neither medical nor surgical, which is prescribed by no school, regular or irregular, nor yet forbidden by any. We refer to nothing more uncommon than flowers. It is the uncommon and bizarre that has usually made up our armamentarium and yet that is not true in this case.

Possibly we should be cautious as to their ever blessed influence and make the exception of certain flowers for hay fever victims; but these are really without the pale, for the hay fever patient is not quite ill enough to deserve flowers and he is usually such a cantankerous customer that no one would think of offering him any. Flowers are for patient and more silent sufferers and for those ill with ailments which are known to sometimes sever the silver cord.

How do flowers work their will upon us? It were a long and involved story, though we doubt not a

most fascinating psychological tale running into all sorts of associational nooks and corners, the secret passages of which are open sesame to appropriate perfumes. The author of the stageworn soliloquy about the effects of a certain jasmine flower could, perhaps, have traced out for us something of the machinery set in motion by a bouquet. At any rate, the idea of a friend goes with both sight and sound of a rose and, as someone has wisely remarked, what every patient most needs is a friend. Just what emotional echoes are aroused by the secondhand flowers sent from a church we should not guess, but it is safe to say that their power for good is not of the highest potency.

In hygiene, also, flowers flourish, for who does not, if he can afford it, seek the lunch room which displays a blossom and a bit of Nature's greenery on its tables. The food tastes better and must digest better and we feel better. One touch of Nature makes the world kin, and whether we are well or ailing nothing makes us so cognizant of our place in the general scheme of things and in our belief that that scheme is managed for good, as its most delicate of structures, the fragile flower. Even the great teacher of centuries ago drew lessons from the scarlet flowers of the field.

If flowers minister to the sick in body, they minister even more to the sick in soul who see their friends undergo dissolution—change. The flowers that never reached the patient in life we feel must reach him in death and bridge the chasm. In the meantime, when humanity feels most frail, the frailest and fairest of the things about us offers more of hope than all things, huge or strong. The flowers we offer to those beyond may wither also in our sight but bloom for them always in fields elysian.

Obituary.

F. R. S. SIR WILLIAM LEISHMAN, K.C.M.G., K.C.B., COMMANDER OF THE LEGION OF HONOR DISTINGUISHED SERVICE MEDAL, U. S. A.

Lieut. General Sir William Leishman, Director General British Army Medical Service, passed away on June 2, 1926, at Queen Alexandra's Military Hospital, Milbank.

Born in 1865, he was the son of Dr. William Leishman, professor of midwifery in the University of Glasgow. He was educated at Westminster School, London, and the University of Glasgow, where he graduated M.B., C.M., in 1886. He entered the Army Medical Service as surgeon and was gazetted captain in 1887, major in 1899 and brevet lieutenant colonel in 1905, having served in the Waziristan Expedition of 1894-5. During this period he devoted himself to the study of bacteriology, more especially with regard to tropical medicine, and on his return to England in 1900 he was appointed assistant professor of pathology at the Army Medical School, Netley. He served there for three years and was then made professor of pathology in the Royal Army Medical College at Milbank, London. This post he held from 1903 to 1913. He was elected a Fellow of the Royal Society in 1910, and in the following year he served as president of the Society of Tropical Medicine and Hygiene, and in 1912 he was appointed honorary physician to the King. From 1913 to 1915 Leishman was a member of the Yellow Fever Commission, West Africa, and he acted for a time on the Medical and Sanitary Advisory Committee for Tropical Africa, while for ten years he was a member of the Medical Research Council. After he became the head of the Army Medical Service he still continued his scientific pursuits. He became chairman of the Foot and Mouth Disease Research Committee appointed by the Minister of Agriculture. Quite recently he was elected president of the Section of Comparative Medicine of the Royal Society of Medicine.

Sir William Leishman will be remembered as one of that small but brilliant body of men who in the space of a few years built up the modern science of tropical medicine and who have done so much to lessen the dangers of the tropics for white men. In this work American medical men of science have also played their parts well. But this work was not Leishman's only claim to fame. He was a pioneer in the cause of improving human health. Perhaps, indeed, his greatest claim to a niche in the hall of fame will rest upon his researches into the cause and prevention of typhoid fever and the results therefrom. Together with Sir Almroth Wright he produced vaccination against typhoid fever. Although their views were at first scoffed at, the great war brought their triumph. As everyone knows in the last war typhoid fever, which had been the scourge and menace of armies in the field from time immemorial, was practically eliminated.

Leishman's other great contribution to medical science was his work in connection with that group of diseases which now bears his name, Leishmaniasis." Before he began his investigations in this direction it was not known that a relationship existed between the Indian kala-azar, black sickness, the Oriental sore socalled, and the Mediterranean type of kala-azar. Leishman in 1900 discovered a body in the blood of a soldier affected with Indian kala-azar which was given the name of the Leishman-Donovan body. This minute parasite is now established as the cause of Indian kala-azar and a similar parasite causes the Mediterranean form of the disease and also Oriental sore or Baghdad boil. Kala-azar is one of the most dreaded of Oriental diseases, but owing to the work of Leishman and his coworkers the cause is known and a method of treatment has been devised.

Leishman was as good an organizer and administrator as a man of science. He was modest and retiring but a good teacher because he possessed the faculty of explaining his results in simple language and the manipulative skill to demonstrate the facts upon which they were founded. His untimely end is a loss to pathology and tropical medicine.

BELLEVUE HOSPITAL IN 1920

Bellevue Hospital

M. W. BROWN, B.S.

New York

In March of the year 1714 a proposition was made to the General Assembly of New York that a "poorhouse" be built. During the previous winter suffering among the poor had been extremely great, and it had been discovered by the church wardens, who were charged with their care, that they were actually perishing from want of food and clothes. So New York City borrowed one hundred pounds sterling for their support for six months. A committee of six members of the Common Council was appointed to consider the matter of a poorhouse. It was twenty years, however, before any decisive steps were taken.

The census of 1731 shows that New York City then contained 1,400 houses and had a population of 8,628. There were many poor, including a large number of vagabonds, beggars and criminals. In the same year the city suffered its third epidemic of smallpox. But not until November of 1734, during the mayoralty of Robert Lurting, did the Common Council appoint a committee to inquire where a house suitable to be used as a workhouse for relieving these conditions might be purchased. In December this committee recommended that such a building be erected on unimproved lands belonging to the city near the estate of the late Colonel Dongan, known as the Vineyard. It was to be called the Publick Workhouse and House of Correction of the City of New York. The site was that upon which the old City Hall now stands. The building was begun in 1735. The committee agreed with John Roomer for carpenter work and materials at a cost of eighty pounds sterling, and fifty gallons of rum, the corporation "to be at the charge for liquor for laying the beams and raising the roof." The building was ready for occupancy early in 1736. And so Bellevue Hospital, whose origin was in this early structure, can lay claim to a history covering nearly two hundred years, and call itself the oldest hospital now existing in the United States.

This old building was fifty-six feet long and twenty-four feet wide. It was two stories high, with a cellar. In the cellar were rooms for those sentenced to "hard labor," and weaving, spinning and carding; a storeroom for provisions; and a "strong room" or cage for the refractory. On the first floor was the dining room; upstairs were rooms for the "keeper" and his family, and an infirmary "to be used for no other purpose whatever." This room, about twenty-five by twenty-three feet in area, on the Broadway side of the building, was the primitive beginning of Bellevue Hospital. It contained six beds. Its first medical officer was Dr. John Van Beuren, whose salary was one hundred pounds a year,

out of which he was expected to supply his own medicaments, drugs, and instruments.

Let us quote briefly from Dr. Robert J. Carlisle's Account of Bellevue Hospital, in the Society of Alumni's Catalogue of the Medical and Surgical Staff: "We would like to have a glimpse of what this hospital was like when its ward was filled; but no clinical record has been left us. It was not the custom in those days to keep very extended or accurate histories. If we could have entered the ward when Dr. Van Beuren was making a visit, however, we would doubtless have seen faces not very strange to a Bellevue man of today. Here is an old and infirm Dutchman, perhaps; there a Frenchman, next an Irishman, and next, perhaps, Lo, the poor Indian, occupies a bed in which today we find John Chinaman. What are the diagnoses? Here are bronchitis and asthma, lues venerea, peripneumonie also, and dropsy of the chest. How did the doctor treat his patients? Let his record tell. Dr. Van Beuren was a Dutchman, born in the city of Amsterdam. He came to this city in the early years of the eighteenth century when twenty-two years of age, a graduate of the medical school of Leyden, and a pupil of the illustrious Boerhaave. . . . He was succeeded by his younger son, Beekman, who held the position at the outbreak of the Revolution. . . . We may be sure that his patients were treated upon the wisest and most enlightened plan. The era of hospital building was just setting in in Europe, and when we remember that his renowned preceptor was one of the first to teach that strict cleanliness and pure air, with simple buildings, are the first and truest principles of hospital management, we may feel assured that the young hospital had been entrusted to proper hands. In those early days the little city of New York had many more than her share of a class of individuals which is not yet entirely extinct, persons who demand of the public both its money and its life. The quacks and charlatans far outnumbered the real physicians. It is said that in 1745 there were at least forty socalled physicians and surgeons in the city, which then had a population of about nine thousand, very few of whom indeed had ever seen the inside of a medical school. . . ."

COL. EDWARD B. DALTON
Surgeon, U. S. A.

The first superintendent of the house was John Sebring, whose official title was Keeper of the House of Correction and Master of the Workhouse and Poorhouse. He lived in the house with his family, and drew a salary of thirty pounds a year, with board and lodging. He had in addition certain privileges and advantages, such as these: for a shilling entrance fee, and seven pence a day for "keep," he received refractory servants and slaves; whipping and other punishment cost one shilling, sixpence, extra, and for discharge another shilling was charged. We find it recorded that in 1764 the keeper received an increase of twenty pounds since there had been no whipper in the house for some time.

"Under this narrow roof," writes Dr. Carlisle, "were confined the maniac and the unruly, the poor, the aged, and the infirm. But 'workhouse' was no misnomer. The vicious were put to hard labor for the common good." An industrial school was carried on for instruction in needlework, knitting, spinning and weaving, and work in iron and leather; a cultivated plot gave opportuities for learning gardening. The teaching was done by inmates who had practiced the various trades taught.

The sanitary condition of the house must have been good. The site was a healthful one, on the outskirts of the city, for in those days Cortlandt Street marked the western city limit, King's Farm was on the north, and to the south and east, at quite a distance, was Beekman's Swamp, which about 1740 was drained and cultivated. On the present Park Row, extending northward and eastward, was the High Road to Boston. Between this and Broadway, on what was called the Commons, stood the almshouse. In 1745 stockades were built for protection against the French and the Indians. These commenced at Mr. Desbrosses' house in Cherry Street and ran in a straight line to Windmill Lane, thence across the city behind the poorhouse to Dominie's Hook, North River. Near the almshouse grounds, but outside the stockade, was a powder house.

Nothing further of consequence is known about New York's first hospital until the time of the Revolution. In 1776 the inmates were transferred to Poughkeepsie until the close of the war. The house was then taken over by the British for the "poor and refractory." After the great fire of September 21, 1776, about three hundred destitute were admitted. A daily paper of the period contains an order sending half a dozen English soldiers, unarmed, to convey an insane woman to the hospital. After the evacuation of the city in 1783, the inmates were returned from Poughkeepsie, and several new buildings were erected to meet the increasing numbers of those needing accommodation.

By 1794, the house had become entirely inadequate for its purpose, and in 1796 a new one was built in the rear of the old building on what is now the north side of Chambers Street. This served its purpose until 1811, when the third almshouse was built, from which time the hospital became the most important department of the institution. On April 17, 1811, during the mayoralty of De Witt Clinton, a special meeting of the Common Council was called

Bellevue Hospital Ambulance No. 3

to consider the purchase of a site for a new almshouse and penitentiary, on an elaborate scale. The site offered was a part of the old Kip's Bay Farm containing about six acres, bounded on the north by what is now East Twenty-Eighth Street, from Cornelius Street to the East River, on a line with the present Second Avenue, thence to Maria Street, between the present Twenty-sixth and Twenty-seventh Streets, to the northerly line of "Belle Vue Place," which already belonged to the city in fee simple. The location itself, the site of the present Bellevue and Allied Hospitals, has a history of unusual interest. In 1765 the property was sold by Peter Keteltas to Jacobus Kip, who conveyed it to Martin Hoffman, who in turn conveyed it about 1772 to Robert Leake, who gave it its name, Belle Vue. In 1783 Lindley Murray came into possession of the site. At the end of the war, he returned to England to live, having sold the property to Brockholst Livingston, who leased it for six years to Nicholas Devise. In 1794 Robert Lenox, a member of the City Board, purchased the property for ten thousand dollars. Dr. John McFarlane, by order of Richard Bayley, Health Officer of the Port of New York, was placed in charge of the grounds when an epidemic of yellow fever threatened the city. This raged until residents fled the town and business was seriously handicapped. Belle Vue was totally unable to care for the victims, and a new "pesthouse" was established on Bedloe's Island. During the summer of 1796 more than seven hundred deaths occurred, and the fever continued until Belle Vue was practically abandoned and the whole city quarantined. The decision to purchase this property for a new hospital and penitentiary was made at the meeting above mentioned, and the sum of three thousand five hundred dollars an acre was paid for it.

No sooner had building been commenced than war with Great Britain was declared, so the work was practically stopped, not to be resumed until the war was over in 1814. On April 22, 1816, the Bellevue committee reported the buildings as ready to receive their guests, and they were formally dedicated and opened on the twenty-ninth. The building material used was Gneiss rock, found on the spot and in the vicinity. The central building had originally three stories, and a north and a south wing. It contained sixty rooms, forty of which accommodated the paupers, a chapel, two dining rooms, a tailor's room, in one of the wings two cells, and the lying-in wards, one for white persons and one for colored. Back of this structure were two more buildings, a workshop three stories high of wood, and a penitentiary of stone. In the former on the first floor the male paupers did weaving; on the upper floors were school rooms and rooms for spinners and leather workers. In the basement women from the prison picked oakum, the white in one room and the colored in another. There was also a Sunday school. North and south of this group of buildings were the hospitals of brick, seventy-five by twenty-five feet, one for male and the other for female patients. Each building contained six rooms. In addition to these structures there were a "dead house," two engine houses, the superintendent's house and garden with a number of outbuildings, a bakehouse, soap factory, carpenter shops, smithy, barns, and houses for stewards, gatekeepers, etc. The cost complete in 1818 was $421,109.56. The whole was enclosed with a ten-foot stone wall and was known as the Bellevue Establishment.

The first addition was made in 1819 at the time of the yellow fever epidemic, when a new hospital was established under the charge of Bellevue physicians at old Fort Stevens on the Long Island shore near Hell Gate. Three years later it was decided that the "fever hospital" should be at Bellevue itself, so additional property was purchased and a four-story stone structure erected. The pauper insane were housed on the first and second floors of this building, and the contagious cases on the fourth. The third was devoted to the staff. At about this time the two brick pavilions formerly used by the medical department were transformed into children's wards.

In spite of the heavy load of duties which they carried, the Bellevue physicians of that day found time to contribute valuable information to the medical press. To quote once more from Dr. Carlisle: "Drake and Brown stand out most prominently among them in this respect. A case of anthrax occurred in the hospital in the summer of 1817, and was treated by incision, and three or four more cases occurred during the next three years. These were reported by Drake in the *Medical Repository*. Brown in 1821 reported a new mode of bandaging fractured clavicles. It would appear from this that Dr. Brown had both medical and surgical services during his tenure of three years. Again in 1825 he reports two cases of fractured patella, one of which was the result of an attempted escape from the prison. A case of dystocia from exotosis of the os ischium, with rupture of the uterus, is another report by Drake. An account of a disease which prevailed in the penitentiary during the fall of 1825 was published by Dr. King, and remarks on delirium tremens, or the "irritative fever of drunkenness," by Trippler. These will serve to show something of the range of cases coming under care in the hospital at that time. But what occupied the attention of the medical staff to the largest extent was the infectious fevers. Yellow fever in 1819 presented its oldtime virulence. Out of a population in the city of 123,706 there were 3,815 cases reported by the Board of Health records. Only five fatal cases occurred at the Fort Stevens pesthouse, however. These are commented upon in a paper by Dr. Drake, printed in the journals of the time. This disease raged again in 1822. The Bellevue physicians looked upon the disease as a noncontagious one, as did also Dr. Douglass of the old Bellevue Hospital in 1796." (It is interesting to remember here that the mosquito origin of yellow fever was not proved until 1900; the date of Dr. Carlisle's history is 1893.) "It was typhus fever,

however, that caused the most havoc in Bellevue. . . . It occurred at three different times—in 1818, 1825 and 1827. The first epidemic was the most severe; it caused many deaths, in both the prison and the almshouse, and it was of a much more asthenic type than the later ones. The death rate is given as one in ten or twelve. . . . Job Young was a colored man in ward five of the hospital, and he was grievously ill of typhus on April 20, 1818. He was in extremis, and an order was given that he be put into a coffin as soon as he died, that his bed might be used by the next patient. It was a short space till this was done, and the coffin was placed with four or five others in the hall, preparatory to removal. Several people passing through the hall a half hour later were startled to hear groans from the pile. Running into the ward a hatchet was procured and the man was soon found. He was alive. He was placed in bed, the doctor called, and every effort made to revive him, but in vain. He lived an hour and a half longer, and returned to his narrow house. This is a glimpse in at the window, and speaks for itself. On investigation, it was proved to be due to the carelessness or ignorance of attendants; and, it may be added, to the excessively difficult and laborious nature of the service. It was ordered that thereafter no body should be removed until the physicians had first pronounced the person dead."

Alms House Hospital in 1848—Bellevue

In 1825 the second epidemic of typhus broke. Dr. Belden and Dr. Drake were both stricken, the former fatally. The epidemic prevailed for four months. At this time came a turning point in the history of the hospital. The Common Council appointed a committee of physicians to investigate conditions at the Bellevue Establishment without delay. A most unfavorable report was made, and the committee of the Council was told some plain truths. They were informed that they were in reality administering a large hospital, whereas they imagined they were conducting only an almshouse and a prison; and the board was convinced that the two must be separated without delay. The Council acted promptly on this advice, and the committee was requested to take immediate charge of the institutions. Changes in the prison and hospital administration followed, and the disease was stamped out for the time being. Dr. Isaac Wood was at this time appointed to the position of visiting physician, and through him many important changes came about. The medical staff was entirely reorganized, and the office of visiting physician abolished and that of resident physician inaugurated. Two assistants resided in the house with him, and all were placed nominally under the direction of a consulting physician and surgeon. Dr. Stephen C. Roe was the first to hold this office. Dr. Wood served for seven years, and succeeded in replacing the struggling hospital on its feet. From this time on it was known as Bellevue Hospital.

The worst plague that ever visited the hospital was in Dr. Wood's regime. This was the visitation of Asiatic cholera in 1832. One-sixth of all the victims in the city came from Bellevue Hospital. There were approximately six hundred deaths at the hospital out of two thousand cases. The disease entered by way of Canada. Forty bodies lay at once in the dead house, because the dead fell so fast that there were not enough living to bury them. Dr. Wood in making rounds had to step over the dead and dying laid out in rows on the floors of the wards. Patients were stricken so suddenly that there were no beds available. Dr. Wood himself contracted cholera and recovered, but the after effects of his illness made it necessary for him to resign his office at the end of a year.

The next fifteen years of Bellevue Hospital were the worst in its history. It was enwrapped in the tentacles of a political octopus and was accounted one of the most prolific spoils of office. The mortality during this period was at an average of twenty per cent. Perhaps it will be wise to pass over these darkest pages of the hospital's history. Those who are interested to know more will find the text of a report made by a commission, appointed to investigate conditions in 1837 by the Common Council, in *Records of the Board of Aldermen,* Document No. 32. In an attempt to remedy conditions, Dr. Benjamin Ogden, who had had successful charge of the hospital for the year previous to the second epidemic of cholera in 1858, was recalled. He accepted the call and arrived at Bellevue on May 13, 1837. The night before he came, he tells us in his report, also printed in the document mentioned above, eight nurses and servants, all of whom were at that time detailed from among the prisoners, had escaped from the grounds, leaving their patients to take care of themselves. "The whole concern was filled with typhus from top to bottom," the report adds. "They were lying in their filthy blankets, destitute of sheets and pillow cases, and in some cases they had not had a change for three months. Requisition had been

made by my predecessor again and again, but no notice had been taken of it. No clothing for the patients—not a change was to be found, and there had not been any Indian meal for poultices for three weeks, and no rags to dress the wounds." Dr. Ogden remained in charge for four months and in that time succeeded in restoring the hospital to the excellent condition in which he had left it in 1835.

The time had now come when it was necessary for the hospital to throw off its encumbrances in the form of the many auxiliary institutions it was maintaining. The first to go was the penitentiary, which was moved to Blackwell's Island in 1836. In 1837 the smallpox patients followed, and in the following year female prisoners were transferred to the Tombs. In 1839 the insane went to Blackwell's Island, and in 1848 the almshouse was transferred. The medical supervision of all these institutions, however, remained invested in the Bellevue staff, and her resident physician was supposed to direct the whole.

Up to 1847 the history of the institution varies little, with its tale of the ever present typhus, culminating in the fearful epidemic of 1847-1848, which carried off many of the hospital staff. Matters again became so deplorable that "Jimmy" Wood, well known physician politician of the time, made efforts to stir up the authorities to action, and the *Evening Post* published a series of letters describing conditions. These letters were signed "G" and were written, so it is believed, by Dr. J. H. Griscom, at one time head of the Health Department. The outcome of the agitation was the appointment of another commission of medical men, to report on conditions and present a plan for reorganization. The members of this committee were Dr. John W. Francis, Dr. James R. Wood, Dr. Joseph M. Smith, Dr. Valentine Mott, Dr. James R. Manley, Dr. F. Campbell Stewart, Dr. Willard Parker, Dr. Stephen R. Harris, Dr. Gunning S. Bedford and Dr. Benjamin Drake. They drew up a plan which was finally adopted; a board of visiting physicians and surgeons was created and placed in authority over the resident physician, and so began the end of the rule of resident physicians. A new medical board was organized, which published its first Annual Report for the year ending December, 1849.

The next important step was the establishment of medical instruction. The socalled Griscom letters in the *Evening Post* had referred to the exceptional opportunities along this line that Bellevue could offer, and an article in the *New York Journal of Medicine* states: "Bellevue Hospital, with its one thousand patients, must be made accessible to students of medicine, and that too without delay. It is a crying shame that such a wide field for clinical instruction should be actually lost to the city, to science, and to the world, merely to subserve paltry party political purposes. . . ." The earliest reference to public instruction in the hospital is to be found in a note in the *Medical Repository* for 1804, which states the fact that a lying-in ward had just been established in the almshouse, and that, as a sufficient number of cases occurred there, Dr. Valentine Seaman had begun a course of lectures on "the obstetric art, including anatomy, physiology, and practical parts, and as this establishment is particularly and exclusively devoted to the education of females, it will be easy for women who practise or intend midwifery to avail themselves of it." One of the members of the first Medical Board gave a course of clinical lectures to a small class in 1844, and this custom was continued by various members until 1852. The new Medical Board had hardly been in power a year before an ampitheatre was planned and formally opened in 1849. The clinic was surgical, with Dr. William H. Van Buren as operator performing a lithotomy. Notice was then given that thereafter students would be admitted without charge to attend clinical lectures on Friday afternoons, and that such clinics would be held by one of the visiting medical or surgical officers of the hospital. A summer course for April, May, June and July was also given.

Within the next few years care and treatment at the hospital improved greatly, and the influx of patients was so great that additional accommodations were a necessity. These were gradually supplied, even to the building of a new "dead house," the upper floor of which became the Wood Pathological Museum. In 1857 the neglected problem of medical instruction was revived, and Dr. Wood announced at the opening of the lecture room in the new pathology building on October 19th that the Medical Board had inaugurated a new era in medical instruction and that the series of lectures instituted would be the first systematized course of clinical lectures ever delivered in this country. (The first clinical instruction in the United States was organized by Dr. Thomas Bond in the Pennsylvania Hospital in 1776.) Tickets for admission to this course were to be had by medical practitioners and students on payment of a fee to the Medical Board. This plan operated for three years only, because in 1860 the old board of ten governors was superseded by a new board of control called the Board of Commissioners of Public Charities and Correction. Among other changes the new board recommended the establishment of a medical college at Bellevue Hospital, which should be "independent of a mere hospital for clinical teaching, thus making it one of the best hospitals and medical schools in the United States, nay, in Europe." These plans were agreed to, and on April 11, 1861, the commissioners gave permission for the erection of a building, and Bellevue Hospital Medical College was the outcome. The First Annual Announcement and Circular, Bellevue Hospital Medical College, New York, 1861-'62, was published in 1861. It contains pictures of the hospital and of the Blackwell's Island buildings, necessary information for becoming a student, opportunities to be had, etc., and closes with a brief paragraph on, Expenses of Living in New York, Etc., from which it may be of interest to quote. "The expenses of living in New York will of course vary according to the views and habits of the student. Comfortable board and lodging may be obtained for from three dollars to five dollars per week. The *necessary* expenses of attending a course of lectures need not exceed $225, exclusive of traveling expenses, and money expended for books, instruments, etc. Students are requested to report at once, on arriving in the city, at the office of the College, at Bellevue Hospital, and pains will be taken to secure for them comfortable accommodations. . . . The gate keeper at the Hospital on Twenty-sixth Street will direct to the office of the College."

The Civil War all but demoralized again the work of the hospital, which had been becoming more and more efficient even in the face of so many obstacles and set backs. Practically the whole staff enlisted. In 1866 the Metropolitan Board was organized, with jurisdiction over New York and Brooklyn, Newtown, Flushing, Jamaica and the whole of Richmond and Westchester counties. Dr. Dalton, formerly Colonel Dalton, who had been in charge of the Depot Field Hospital of the Army of the Potomac at City Point on the James River, was appointed Sanitary Superintendent. It was during this service that Dr. Dalton had the idea of applying to civic conditions the main principles governing in a field hospital the transportation of the wounded. And so the ambulance came into being. His scheme submitted to the Commissioners for the organization of an ambulance corps was accepted, a competition among carriage makers for the best ambulance plans was announced, in which the Abbott-Downing Company was successful, and on June 30, 1869, the Medical Board of Bellevue held the first examination for ambulance surgeons. During the same month the first city ambulance service in the world was inaugurated. Eight years later other New York hospitals followed Bellevue's lead in this respect, the New York and the Roosevelt Hospital in 1877, St. Vincent's in 1879, and the Presbyterian in 1880. The corps at first had two ambulances, but these were soon entirely too few, so in 1870 five more ambulances were added. This was the year when the new Reception Hospital in Centre Street was opened.

SCHOOL FOR NURSES

The next important step in the history of the hospital was the establishment in May, 1873, of the New York Training School for Nurses Attached to Bellevue Hospital, under the sanction of the Medical Board, by a committee of women of the State Charities Aid Association. Dr. Carlisle writes: "Neither the practice of antisepsis nor the application of modern sanitary laws, nor both together, could have brought the hospital to its present efficiency if it had not been for the Bellevue Training School; indeed neither of these is practicable except by means of intelligent agents. Prior to the establishment of this school, the nursing of the sick was scarcely superior to a pretense. The nurses, or rather those employed as such, were nearly without exception to the last degree incompetent. They were ignorant, indifferent, dishonest; they were eye servants. Sairey Gamp and her partner, Mrs. Prig, were ubiquitous. They 'drank fair,' and only attended to their patients when 'so dispoged.' This state of things had grown out of the employment of people from the penitentiary as attendants, nurses, and general helpers about the hospital, and was an heirloom from the primitive times when the hospital itself was only an economical attachment to that institution and the poorhouse. Most of them had just served enforced time on the island, had worked without pay, and for the sake of the board and lodging and the dishonest perquisites they obtained." The new training school committee secured a house near the hospital for a home for the nurses, and made every effort to find a competent person for a superintendent of the work. After much deliberation, they at last obtained Helen Bowden of the University College Hospital, London, known in England as Sister Helen. She had an able assistant in Miss Van Rensselaer. There were only four applicants for the position of head nurse, and Sister Helen accepted only three of them. Twenty-nine applied for admission to the school, and of these ten were rejected. The first class was graduated in 1875 with six members.

In 1887 Mr. D. O. Mills presented to the Department of Public Charities and Correction a sum of money to pay for the erection of a training school for male nurses. This was opened the same year and placed under the supervision of the women's training school, a plan that was continued until the graduation of the first male class.

Additions to the hospital made in later years were the new amphitheatre in the dome erected in 1890 with a seating capacity of nearly three hundred; the Crane Operating Room, the gift of Mrs. Mary Crane Mills in memory of her father, Dr. John J. Crane, formerly visiting surgeon to Bellevue; The Sturges Pavilion, the gift of Mr. and Mrs. W. H. Osborn; the Marquand pavilion erected in 1883 by F. and H. Marquand in memory of their brother, Josiah Penfield Marquand; the Townsend pavilion, presented to the hospital by Mrs. Richard H. L. Townsend in 1887; the Annex erected by Miss M. H. Dehon; the chapel of Christ the Consoler, also the gift of Mrs. Townsend, and the Roman Catholic Chapel; and pavilions for alcoholics, for the mentally diseased, for those suffering with erysipelas, and a number of others, all built before 1900.

ALLIED HOSPITALS

In 1902 the New York Legislature created the Department of Bellevue and Allied Hospitals, which was to comprise the Harlem, Fordham and Gouverneur Hospitals. The buildings were erected in the above order. A new Bellevue was commenced in 1906. In November, 1908, a new pavilion for medical cases with four hundred beds was opened, and in 1910 a new morgue, a pathology laboratory and a dormitory for men were completed. Later a number of new administrative buildings, a pavilion for surgical cases, a new amphitheatre and x ray department, and pavilions for diseases of the eye, ear, nose and throat have been opened. There is also a new psychopathic department, and one for the care of alcoholic patients. Of course, the ambulance has been brought up to date with the rest of the hospital equipment, the old horse-drawn ambulance having been superseded, first by gasoline automobiles, and finally by electric ambulances.

No more fitting tribute could be given to the work of Bellevue Hospital, pursued in the face of almost interminable obstacles and difficulties for nearly two hundred years, than to quote the modest conclusion of Dr. Carlisle's excellent and interesting little history. "A notable part of Bellevue's history has not been related," he writes. "An abler pen would have to tell of her achievements in the fields of medicine and surgery. Of the bold surgery of Mott; of the artistic surgery of Wood—periosteal surgery, inseparably connected with the name of Wood, had here its birthplace; of the skill and precision of Flint in medical diagnosis, all the world has heard. And Clark in medicine, Van Buren in surgery, Barker in obstetrics, Hamilton a master in the plastic art—these continue the brilliant record. These are Belle-

vue's laurels, and to every man of Bellevue they will ever be an incentive to great things. They will be his inspiration and their guiding principle his motto —*Natura arte.*"

News Items.

Mt. Vernon Opens Dog Clinic.—Mount Vernon, N. Y., has opened its first clinic for the vaccination of dogs against rabies. It will be conducted on Tuesdays and Fridays from ten to eleven o'clock in the morning and from three to four in the afternoon.

Gift to Maine General Hospital.—The trustees of the Maine General Hospital at Portland have announced a gift of one hundred thousand dollars for enlargement of the institution from Cyrus H. K. Curtis of Philadelphia, the publisher. Mr. Curtis was born in Portland.

Work on Hospital Branch Begun.—Construction has been commenced of the new five hundred thousand dollar branch of St. Luke's Hospital, New York, which is being erected in Byram Woods, Harrison. The plans call for a structure 220 by 130 feet on a tract of land containing about two hundred acres donated to the hospital by Mrs. Hicks Arnold. A gift of one million dollars supplemented that of the land.

Information for Medical Visitors to New York.—The Committee on Medical Education of the New York Academy of Medicine has printed for distribution in this city and in European medical centers a leaflet of main facts of interest about the Academy and the advantages it offers to medical strangers in New York City. The leaflet has been printed also in French and German, and a half page reprint of it appears in the Spanish edition of the *Journal of the American Medical Association.*

Missouri Valley Medical Society Will Dedicate Building.—An interesting feature of the annual meeting of the Medical Society of the Missouri Valley, to be held September 15-17 in Omaha, will be the dedication of the new eighteen story Medical Arts Building. All of the lectures and diagnostic clinics will be held in the auditorium of this building. An elaborate commercial exhibit will be located on the same floor. Among the speakers at the meeting will be Dr. Hilding Berglund, professor of internal medicine at the University of Minnesota; Dr. Irving S. Cutter, dean of Northwestern University College of Medicine; Dr. McKim Marriott, professor of pediatrics of Washington University, St. Louis; Dr. E. C. Rosenow, University of Minnesota, Mayo Foundation; Dr. Gabriel Tucker, bronchoscopic clinic, University Hospital, Philadelphia; Dr. R. L. Haden, professor of experimental madicine at the University of Kansas; Dr. E. H. Skinner of Kansas City; Dr. William Pusey of Chicago; Dr. C. R. Morre of the University of Chicago; and Dr. Jabez N. Jackson, president elect of the American Medical Association, of Kansas City.

Connecticut State Medical Society Meeting.—The program of the Clinical Congress of the Connecticut State Medical Society, to be held in New Haven, September 21-23, are now ready for distribution. Inquiries for information should be addressed to Dr. Creighton Barker, 129 Whitney Avenue, New Haven, Conn. The meetings will be held at Sprague Memorial Hall in College Street, corner of Wall. The opening session of the Congress will be at 10 A.M., daylight saving time, on Tuesday, September 21st. The fee for attendance will be ten dollars, which will include admission to all sessions of the Congress including a Smoker on the second evening. It will include also luncheon on each of the three days, parking space, and garage, and a copy of the printed abstracts of the papers presented. It will not include use of rooms in the dormitory or breakfasts or dinners in the dining hall.

Queensborough Diphtheria Prevention Drive.—The Department of Health of the City of New York has inaugurated in Queensborough a drive against diphtheria. During the months of July and August a special effort is being made to immunize as many of the preschool age children as possible. In eight of the Department of Health stations, on appointed days and hours, the Department of Health physicians will be on duty to administer immunizing treatment to all those applying.

New Dormitory for Blind Workmen.—The New York Guild for Jewish Blind recently dedicated the new dormitory for blind workmen at 46 West One Hundred and Twentieth Street. This will be supplementary to the work already established in the vacation camp for the blind at Rye.

Centenary of Laënnec.—The Academy of Paris has commemorated the centenary of the death of Laënnec by publishing a second edition of his great work, *Le traité d' auscultation.* On August 12th a *fête bretonne* was held at Ploaré, formerly the parish of Laënnec, which included a service in the church at Ploaré, an official procession to the grave, addresses, a banquet presided over by M. Delécluse, president of the committee, and an afternoon visit to the *Manoir Kerlouarnec,* where Laënnec died.

National Board of Medical Examiners Elects Officers. At its annual meeting, the National Board of Medical Examiners elected the following officers: president, Admiral E. R. Stitt, Surgeon General of the U. S. Navy; secretary, Dr. J. S. Rodman; director and treasurer, Dr. Everett S. S. Elwood; new members of the Executive Committee, Dr. A. S. Begg, Dean of the Boston University School of Medicine; Dr. J. B. DeLee, professor of obstetrics at Northwestern University Medical School; Dr. Otto Folin, professor of biochemistry at Harvard University Medical School, and Dr. Louis B. Wilson, director of the Mayo Foundation.

Health Exhibit at the Sesquicentennial.—The Philadelphia health exhibit at the Sesquicentennial Exposition occupies 8,400 square feet of floor space. Medicine, surgery, dentistry, occupation diseases, nursing, hospital care, and pharmacy all have major exhibits. In the pharmacy exhibits are shown two drug stores, a modern, up to date one and an antiquated one. There are many beautiful and instructive charts and posters illustrating all kinds of health problems. A first aid station, with its personnel drawn from the staff of the Philadelphia General Hospital, is in operation. John Eckles of the Health Department of Philadelphia is director of the exhibits.

Annual Meeting of Association of American Medical Colleges.—The thirty seventh annual meeting of the American Association of Medical Colleges will be held, October 25th-27th in Cleveland, Ohio. The Hotel Statler will be headquarters. Among the speakers will be Dr. John A. Wycoff, University and Bellevue Hospital Medical College; Dr. Franklin D. Barker of the University of Nebraska; Dr. Burton D. Meyers of the University of Indiana; Dr. H. G. Weiskotten of Syracuse University; Dr. Martha Tracy of the Woman's Medical College; Dr. Frederick C. Zapffe; Dr. Albert T. Lytle of the University of Buffalo, Dr. J. W. Pryor of the University of Kentucky, and Dr. W. F. R. Phillips, of the Medical College of the State of South Carolina.

Personals.—Dr. Robert Condy, of Dublin, Ireland, has recently been a visitor in the United States. He is investigating health methods under the auspices of the International Health Board.

Dr. William Martin Richards of New York City has been provisionally appointed assistant physician at Sing Sing. Dr. Richards served as a medical officer overseas during the World War and at one time was also a member of the British Army service.

Dr. James C. Walsh, formerly assistant superintendent of the Onondaga County Tuberculosis Sanatorium, has been appointed superintendent of the Jefferson County Tuberculosis Sanatorium.

Dr. A. B. Emmons, 2nd, has resigned his position of director of mercantile health work at the Harvard Medical School and is travelling in Switzerland.

A recent arrival in New York City was Mme. C. F. Pedroso, wife of the Brazilian surgeon. Mme. Pedroso, who acts as her husband's assistant, said that he would soon follow her for a visit to this country. Dr. Pedroso's specialty is cancer.

Clyde L. West, formerly of the U. S. Army Medical Corps, who was one of the yellow fever volunteers with the late Major Walter Reed, has been placed on the roll of the War Department for the remainder of his life at a salary of one hundred dollars a month in lieu of all pensions. The War Department announced that this was "in special recognition of the eminent service he rendered, the suffering he endured, and the permanent disabilities contracted by him in the study of yellow fever in Cuba in 1900."

Book Reviews

RECTAL DISEASE

Rectoscopie; Sigmoidoscopie. By R. Bensaude. Second Edition. 115 Illustrations. Paris: Masson et Cie, 1926. Pp. 178.

This is by far the most exquisite atlas of rectosigmoidoscopy that has ever been offered to the profession. Dr. Bensaude, who was one of the pioneers in rectoscopy, relates in his introduction the difference in the status of this method of examination now as compared with about fifteen years ago. "In 1907, when I was preparing my first article on rectocolonic endoscopy, there were in France but few surgeons or physicians practising rectoscopy; today their number is legion." Considerable enlargement has been made both in point of text and illustrations on the first edition which appeared in 1910. The illustrations, particularly the colored ones, are very well selected and extremely well done. The text is clear and very interesting. The manipulation of the scope and the comments on biopsies are instructive. No one interested in diseases of the rectum or colon can consider his reference library complete unless it contains this book which is indeed a worthy contribution to proctology.

RECTAL DISEASES

Handbook of Diseases of the Rectum. By Louis J. Hirschmann, M.D., F.A.C.S. Fourth Edition. 252 Illustrations. St. Louis: The C. V. Mosby Company, 1926. Pp. 403.

The new fourth edition of this book is, like its predecessor, a well written book, particularly in so far as the general surgeon is concerned since the author seems more concerned with the operative rather than the nonoperative treatment of the various rectal diseases. Rather strange is the fact that but one small paragraph is devoted to the treatment of the most serious rectal disease, cancer of the recum. Considerable study is required to detect evidence of the book having been revised or rewritten to any great extent since the only changes noted consists of the omission of one chapter from the third edition and the addition of a few pages on sacral anesthesia. In this connection the use of all metal syringes has long been obsolete with most surgeons though the author still shows them in the illustrations. Apparently not much review has been made of the literature which has appeared during the six years intervening since the last edition since new methods and facts are conspicuous by their absence. The injection treatment of hemorrhoids is very briefly touched upon while the operative treatment is given in detail. This does not seem fair to the reader who reads that the author has used this method successfully "for many years in personal practice." Mosby Company have, as usual, put out a very well printed and bound book.

HAIR

Your Hair and Your Health. By Oscar L. Levin. New York: Greenberg Publisher, Inc., 1926.

The entire subject of the care of the hair and its numerous diseases and malformations is well covered in a space of one hundred and sixty-three pages. There are fourteen chapters which include the anatomy and physiology of the hair, general hygiene, baldness from constitutional causes and local infection, premature and senile baldness, canities and abnormal types of hair. One chapter is devoted to occupational affections of the hair. The last chapter contains an excellent summary of the book in the form of questions and answers.

The author lays great stress upon the relationship of hair growth to the general health. While some may think that his ideas in this respect are carried a little too far, they will admit that the advice relating to general health is useful and sound. From the physician's standpoint there are a few statements which can be challenged. In discussing baldness in spots (alopecia areata) he speaks of the use of antiseptics to destroy infection, when there is a pretty general agreement that the disease is not due to any local infection.

The book is a readable one, the author's command of the English language being unusually good. It should appeal to the intelligent layman. The work of the publisher is very satisfactory.

INFECTION

Acute Infectious Diseases. By J. D. Rolleston, M.D. (Oxon.) Physicians and Surgeons Book Co., 353 West 59th St., New York City.

A book of this sort is a pleasure to read. It is the product of vast experience and is excellently written. The large reference list of articles compiled from many lands commends itself for induction of cosmopolitan thought. For diphtheria alone over eighty-five authors have been quoted. This international scope of delineations is invaluable.

An asset to the book is the lack of illustrations for, as Dr. Rolleston maintains rightly, the bedside is the place to study the morbid conditions. A copy could well be in the reference library of every isolation hospital and on the shelves of physicians who come in contact with infectious diseases. It is a true reference book; consequently it is best in the hands of the professor or instructor rather than in the hands of students as a text. In this country first hand knowledge with the notes of clinicians suffice for the majority of students whose medical course is of four years' duration.

Infections usually treated at home or in general hospitals, such as influenza, puerperal fever, acute poliomyelitis and epidemic encephalitis are not included.

Each elucidation of a disease begins with the synonym in French, German, Dutch and Italian. Then follow in order the definition, historical note, etiology, bacteriology, morbid anatomy, symptomatology, complications, tests, diagnosis, differential diagnosis, prognosis, prophylaxis and finally treatment.

The section on typhoid is most complete: no detail is overlooked. There is comment on the rupture of the rectus abdominis being overlooked for intestinal perforation. The fairly rare cases where coli infection may cause typhoid like symptoms are mentioned. In fact the book is thoroughly up to date.

Difference of opinion on some issues is inevitable. For example, on page 48, spraying the throat with

staphylococcus to change the flora in the throat is to some not advisable. There are two pages devoted to the "Fourth Disease." While it is true that we often come across puzzling conditions that are neither scarlet fever nor measles apparently, and some cases like these clear up after a dose of castor oil, the Fourth Disease is not generally recognized by name. In other words Filatow-Dukes or the Fourth Disease exhibits none of the criteria by which diseases are named. There is no constant symptomatology, no definite syndrome, no one constant marking such as Koplik's spots that would give these strange, irregular conditions a right to the title of disease.

Altogether, the book is presented in an interesting manner, has enviable diction, and airs varying schools of thought. It is a very careful work and shows where ideas are in the experimental stage, leaving open to opinion the choice of procedure.

OBSTETRICS

A Handbook for Senior Nurses and Midwives. By J. K. Watson, M.D. 554 Pages with Illustrations. Oxford University Press, 1926.

The author states "his object has been to make this volume largely supplementary to his handbook for nurses and his handbook for midwifery . . . and to go more into detail than would be possible or desirable in the elementary book." This preface at the start disarms criticism. The book is too detailed and exhaustive for the teaching of undergraduate nurses but for postgraduate or supplementary work it undoubtedly fills a much limited field of instruction. Perhaps the usefulness of this book is greater in England than this country where a feeling is against instructing a nurse in the same manner as a medical student.

However, the book is well written, splendidly illustrated, and concisely and clearly covers the subjects considered. This naturally would be expected of the author who has always had a natural aptitude for clear thinking and concise and lucid exposition of his subject.

* * *

Modern Views on the Toxemias of Pregnancy. By O. L. V. de Wesselow and J. M. Wyatt. 99 pages. New York. Paul B. Hoeber, Inc., 1923.

This is a small volume which intends to consolidate the most modern ideas on the toxemias of pregnancy. It contains in concise form the most prevalent theories as to the etiology of these conditions.

The larger part of the book is devoted to the body chemistry during pregnancy and the deviations from normal in the toxemias, with a description of the various laboratory tests to determine these deviations from normal. This portion of the book is handled in a much more lucid and satisfactory manner than that given over to the treatment of these conditions.

TRANSACTIONS

Transactions of the American Climatological and Clinical Association. For the Year 1925. Volume XLI. Printed for the Association, 1925. Pp. xxxvi-216.

Among the more than twenty articles contributed by just as many authors on most varied subjects, those of greatest interest are the following: Differential Diagnosis Between Hyperthyroidism and Psychoneuroses, by Edward A. Strecker; Iodine in the Treatment of Disease of the Thyroid Gland, by David Marine; Röntgen Ray Treatment of Whooping Cough, by Henry I. Bowditch and Lawrence Smith; Extrapleural Thoracoplasty for Pulmonary Tuberculosis, by Howard Lilienthal; The Diagnostic and Prognostic Significance of Pleurisy in Pulmonary Tuberculosis, by F. H. Heise and Lawrason Brown; Increased Permeability of Vessel Walls as Frequent Cause of Pulmonary Tuberculosis, by F. M. Pottenger; The Recognition and Treatment of Neurocirculatory Asthenia in Civil Life, by George Morris Piersol; Tonsillar Infection as a Cause of Meniere's Disease, by Judson Daland; and The Present Status of Chlorine Gas Therapy, by Edward B. Vedder.

MEDICAL RESEARCH

Studies from the Rockefeller Institute for Medical Research. Reprints, Volume LVI. New York: The Rockefeller Institute for Medical Research. Pp. vi-630.

This publication contains the results of the investigations conducted at the Rockefeller Institute, or elsewhere under its grants. They are reprints of articles published in several scientific journals. The subjects covered are pathology and bacteriology, biophysics, chemistry, general physiology, studies of cases in the Hospital of the Rockefeller Institute, and animal pathology. The majority of these articles deal with subjects of an extremely scientific nature, so much so that they are of little practical utility to the general practitioner.

Those of more general interest are Yellow Fever Research, 1918-1924: A Summary, by Noguchi; Studies on Urobilin Physiology and Pathology, by Elman and McMaster; The Biliary Aspects of Liver Disease, by Rous; The Use of Urea as a Diuretic in Advanced Heart Failure, by Crawford and McIntosh; Rheumatic Fever, by Swift; and The Problem of the Etiology of Herpes Zoster, by Cole and Kuttner.

MEDICAL ANNUAL

The International Medical Annual. A Year Book of Treatment and Practitioner's Index. Forty-fourth Year 1926. New York: William Wood and Company. Pp. xii-555.

This annual publication needs no introduction to the English speaking medical world. As usual, its list of contributors includes many shining lights of the medical profession, mostly from England. The medical and surgical literature of America, England, France, and Germany is reviewed. Attention is devoted largely to the treatment of the individual case, with attention to the new methods of early diagnosis, and the prevention of disease. The illustrations are excellent and numerous.

The advances in medical treatment discussed include the persistent use of ethyl esters of chaulmoogra oil in leprosy, the serum treatment of yellow fever and a prophylactic vaccine, rutonal in epilepsy, tryparsamide in syphilis, mercurochrome intravenously in erysipelas and ulcerative endocarditis, adrenalin in heart block, sanocrysin in tuberculosis, and arsphenamin in pulmonary spirochetoses. The insulin treatment of diabetes still requires the aid of dietetic treatment.

Hemorrhage of the newborn responds admirably

to injections of whole blood. Faith is being lost in the value of blood transfusion in pernicious anemia.

Cerebrospinal fever responds well to suboccipital puncture. Lethargic encephalitis is still obstreperous to treatment, but the treatment of acute anterior poliomyelitis has become more effective, especially with the use of physiotherapeutic methods. The value of open air treatment in tuberculosis and, especially in cardiac rheumatism of children, is emphasized. Muscular relaxation is recommended for insomnia and "weaning" methods for chronic alcoholism.

In angina pectoris, surgery is a mistake; in thyroid disease it is proving its usefulness. There is a new method of collecting blood shed during an operation for reintroduction by transfusion. The new operative treatment of mitral stenosis is discussed. The modern treatment of fracture of the neck of the femur and the operation for pruritus ani are reviewed.

The importance of the nondescent of the diaphragm in the production of postoperative pneumonia is emphasized. The use of an indwelling duodenal tube in ileus is advocated. The differential diagnosis of genuine chronic appendicitis is discussed thoroughly.

The new methods in neurologic surgery are reviewed, and old ones reexamined. Ureteral stricture is recognized as a definite pathologic condition. Intravenous urotropin is recommended for postoperative urinary retention. Painful feet and their treatment receive attention. Ophthalmology also comes in for its share of discussion, as does also the treatment of venereal diseases. The various anesthetics are discussed quite fully. Obstetrics and gynecology does not offer much that is new or startling. The outstanding event of the year, the work of Gye and Barnard on the etiology of cancer, is discussed.

As regards the newer methods of diagnosis, the relationship of angina pectoris and coronary thrombosis is taken up. Five cardinal indications for the diagnosis of pulmonary abscess are described. Other innovations are celioscopy, the use of lipiodol for the x ray diagnosis of spinal cord tumors, and cholecystography for the x ray demonstration of the gallbladder.

On the whole, a book of great value to the general practitioner and specialist.

LABORATORY METHODS

Manual of Clinical Laboratory Methods. By Clyde Lottridge Cummer, Ph.B., M.D. 2nd edition, revised. Lea & Febiger, Philadelphia and New York.

The aim of this book by the associate professor of clinical pathology at the Western Reserve School of Medicine, Cleveland, is to have it a textbook for medical students. It may also well serve as a guide for physicians and laboratory technicians with its concise, readily available and intelligible directions for useful diagnostic methods.

As a rule several ways of performing tests, that are in use in different parts of the country, are given, rather than one alone. For the Wassermann tests Kolmer's method is presented which, however, is not thought superior to standardized methods in use in other laboratories such as those of the Health Departments of New York city and State. Many other statements reflect a personal opinion. For example, some people put amboceptor into sheep blood cells all at once instead of gradually as stated here. Again, saline is employed for antigen washings rather than distilled water. The method of cleaning Berkefeld filters is not especially helpful.

No mention is made of Dr. Park's toxinantitoxin for diphtheria, nor of Ramon's "anatoxin" tests.

The section on blood chemistry is clearly written and in an attractive, easily assimilated form. The résumés at the end of each test are good for teaching purposes and for the average technician who is generally unable to wade through a mass of statements and calculations, and depends for learning on actual performance of work as shown him by another technician.

The differentiation between parasites is tabulated. There are abundant illustrations of apparatus and material under discussion, such as microscopic sediment and parasites. The diagram of the method for spinal puncture is well drawn as are other illustrations.

A table giving the direct conversion of c. c. of thiosulphate required in the blood chemistry test, to sugar percentage, simplifies the determination of sugar in the blood.

It is a distinct aid to mention the companies that made the chemicals and apparatus delineated in the book as was done. Weights and measures tables are put in the appendix.

It is a moot question, that of having technicians use books with diagnoses, as there is a great tendency to match results and not turn in to the physician the original findings. It is a valuable book in the hands of a conscientious laboratory worker.

PHYSICAL SIGNS

A Manual of Normal Physical Signs. By Wyndham B. Blanton, M.A., M.D., Associate in Medicine, Medical College of Virginia. The C. V. Mosby Co., St. Louis Mo.

Every medical school has its own method of crossing the gap between the preclinical and full clinical instruction. This book is just such an example.

There are no illustrations by which a student can visualize quickly the detailed information. Most clinicians would take a book like this and use it for outline work putting over the subject to the students by practical application, and then embed the information in practical quizzes.

The index gives a full description of the contents and the headings are as follows: Regional anatomy, sound, inspection, palpitation, percussion, auscultation, constitutional signs, head and breast, respiratory system, heart, bloodvessels, blood pressure, sphygmography and electrocardiography, esophagus and abdomen, back, extremities, lymphatic system, nervous system, rectal and vaginal examination, youth and old age, and order of physical examination. Each of these headings has a list of subheadings which indicate the full scope of the work.

The author feels, as he states in the preface, that in textbooks "normal signs are so intermingled with pathological signs that the average beginner in this subject finds himself hopelessly at sea in attempting to discover a clear description of just the normal." He adds that class room instruction is relied upon to amplify the skeletal arrangement. With the mass of work on hand in medicine it is better to let each clinician provide his own emphasis.

Medicoliterary Notes.

Dr. Ellice McDonald of Philadelphia had an interesting letter in the *New York Times* for Sunday, June 13, on the problem of the family physician. He advocates better education of him and his colleague, the specialist, in the processes of life. "When the profession of medicine recognizes this salient fact," he concludes, and applies the atomic theory to cell processes, then the problem of the family physician and the specialist will solve itself in the fuller knowledge of life and its deviations in disease."

The National Tuberculosis Association has recently issued the sixth edition of its pamphlet on Standards for the Diagnosis, Classification and Disposition of Cases of Pulmonary and Glandular Tuberculosis. The text has been rewritten and revised so that the edition is practically new. The pamphlet may be secured free of charge by any physician on request to his state tuberculosis or public health association.

A fund has been authorized by the Italian Cabinet to be devoted to the encouragement of authors, and will be a part of the budget of the Department of National Economy. Prizes will be given to writers and institutions producing works considered to be of value to the country's culture or industry.

* * *

Another use for ultra violet rays has been found at the London Zoo, says the *Daily Mail.* Because his surgical boots are not curing his rickety legs quickly enough, the young pigmy elephant is undergoing treatment. For five minutes daily he is drenched with ultra violet rays from a powerful mercury vapor lamp. His further treatment includes daily massage with cocoanut oil, and a diet of oranges, grapes and bananas, biscuits, and two buckets of condensed milk.

* * *

At the recent conference of German physicians at Eisenach, a resolution was adopted against all forms of prohibition laws, based on the view point that legal restrictions on personal freedom inevitably lead to race demoralization. The meeting was attended also by many prominent temperance advocates. The conference almost unanimously voted in favor of an educational campaign against intemperance by school propaganda, the encouragement of sports, and the curbing of the "treating" habit.

* * *

Advice to the Expectant Mother on the Care of Her Health, is the title of a practical little pamphlet written by Dr. F. J. Browne, professor of obstetric medicine in the University of London and director of the obstetrical unit at University College, London. The pamphlet discusses the benefits of antenatal care, normal pregnancy, the hygiene of pregnancy, its common disorders and their treatment, preparations for confinement, and hints on breast feeding. E. S. Livingstone of Edinburgh is the publisher.

* * *

This season's advertisements for tourists, issued by the American Express Company, contain leaflets calling attention to ways of relieving animal suffering, especially in countries where horses and other beasts of burden are cruelly overworked and maltreated. Among the suggestions made by the express company are: Refuse to hire a cab whose horse shows signs of the lash, abuse or neglect; stop the cab and refuse to ride with a man who beats his horse.

* * *

Elements of Metabolism; Metabolism Testing, What Is Normal? Conspectus of Metabolism Queries, Tables for Computations is the title of a pamphlet by Frank B. Sanborn, formerly professor in Tufts College, and published by Sanborn Company of Cambridge, Massachusetts.

* * *

The Board of Managers of the Manhattan State Hospital have recently issued their twenty-first annual report covering the year ending June 30, 1925.

According to press reports, the first commercial air ambulance has been completed for use by the German air service at the Dornier-Wal plant at Friedrichshaven. It is a seven passenger, high speed plane, the interior of which is enameled to facilitate disinfection. It contains two berths for the seriously wounded, four invalid chairs, and space for two attendants.

* * *

At a recent meeting of the British Medical Association, the question was humorously discussed as to why almost all British physicians wear moustaches. A count was taken at the meeting and it was found that only about twenty of 250 delegates were shaven on the upper lip. One delegate remarked that, judging from the large number of moustached doctors, the General Medical Council might in the near future be expected to decree that all physicians must wear moustaches.

* * *

According to an article in a recent issue of *Chemistry and Industry,* fuel gas has been successfully produced from sewage sludge in Essen, Germany. The process is controlled by bacterial action and regulation of temperature. A number of plants in Essen are producing gas by this method, ranging from 250,000 to 600,000 metres a year. The gas is used as a constituent of town gas, as a fuel gas at the works, or is compressed into cylinders.

All truck and delivery horses in Berlin, Germany, which are owned by the city, are having a three weeks' vacation this summer on a three hundred acre municipal estate containing a horse sanitarium in charge of a corps of veterinarians. Officials in charge of the estate, formerly the seat of a nobleman, says that it pays to give horses a rest by the same token that it pays to give human beings a vacation. The animals get all the oats and hay they can eat, and prance about the meadows or loll in the shade under the trees. Many private business concerns are adopting the idea, sending their horses to the same farm while the drivers are on their vacations.—*N. Y. Times.*

The Committee on Medical Education of the New York Academy of Medicine has published a valuable little book entitled *Opportunities for Clinical Study in the Hospitals of New York City with Transportation Guide.* It contains transit maps of Manhattan and Brooklyn, lists of hospitals, clinics, undergraduate medical schools, graduate medical courses, special internships or residences, fellowships, and dental internships offered in New York hospitals, and other information of value. The entries in the above mentioned lists are annotated with descriptive notes.

Abstracts from Current Literature

CARDIOLOGY

Alpha Lobelin.—H. Reichle and K. Peters (*American Journal of Surgery,* Vol. XXXIX, No. 10) conclude, from their personal experience with the drug, that in Alpha Lobelin we have a specific, powerful and reliable stimulation of the respiratory center. To date no evil results have been noted from the drug, although overdosage must be guarded against. In general Alpha Lobelin gives a very quick response—within one to one and a half minutes of injection. Cumulative action is impossible as the drug is rapidly destroyed in the body; within three quarters of an hour at the most, so it seems to be possible in all cases to repeat the dose.

Blood Transfusion.—G. G. Ward (*American Journal of Surgery,* Vol. XXXIX, No. 10) desires to emphasize the following:

1. That blood transfusion should be employed as a *routine* prophylactic measure before operation much more frequently than is the present practice, especially in gynecological cases.

2. That every interne on graduation from the hospital should be competent to make the necessary blood typing and blood matching technic, and to perform a blood transfusion, preferably by the direct method. The blood examination is often necessary at night or on holidays when the laboratory force is not available. This implies instruction and the skill which comes with practice.

3. That five hundred c. c. of blood is sufficient in a large proportion of cases for a prophylactic transfusion, and thus this amount is not sufficient to cause the donor distress.

4. That the amount of blood lost in many gynecological operations is not always appreciated by the operator and is a factor that should be considered where patients have a lowered blood state.

5. That while post transfusion reactions occur in about twenty-five per cent. of cases they are usually not of a serious type provided that the donor's and recipient's blood have been directly matched, and that they do not appear to mitigate the benefits of the transfusion.

6. That if this procedure is more generally adopted, it will result in an appreciable improvement in our mortality and morbidity statistics.

Treatment of Varicosities with Intravenous Sclerosing Injections.—R. Jung (*Schweizerische medizinische Wochenschrift,* November 26, 1925) states that the dread of thromboses and embolisms has been the reason for the objection to the treatment of varicosities by the phlebosclerosing method of injection. In the usual descriptions of this method the remark is often made that there results an intravenous thrombosis. This immediately suggests the thought of thrombophlebitis and fatal embolism. However, it is now definitely known that the phlebosclerosis, as it occurs after the injection of a chemically irritating solution into the varicosities has nothing in common with a true thrombophlebitis, in which the organization of the thrombi is complicated by infectious noxa and embolism is always to be feared. The phlebosclerosis is a productive, adhesive and organizing phlebitis.

As the result of the primary injury of the endothelium there develops a general cellular proliferation in the vein wall, in which not only the endothelial cells, but also the muscle fibers are involved. The vein wall thickens gradually and finally leads to obliteration of the lumen of the vein. The incidental thrombus formations are always of a secondary nature, cling from the very beginning to the diffusely injured vein walls, are held firmly and pierced by the proliferating intima and are eventually changed into a fibrous strand; a migration of such thrombi is not even thinkable. If one also bears in mind that as a result of purely mechanical factors, such as tortuosity and branching of the sapheneous vein and its retarded and often retrograde circulation of blood, a displacement of thrombi is hardly possible, it will be found to bear out the fact of experience, that even with a true infectious thrombophlebitis with palpably demonstrable thrombi of the superficial veins there is no great danger of embolism, and that, as a matter of fact, only thromboses of the deep veins, which are not at all affected in the treatment of varicosities, need not give cause for alarm.

The author has found two good phlebosclerosing remedies in sodium salicylate and sodium chloride. Strengths of fifteen to forty per cent. solutions are injected in amounts of three to five c.c. per injection. The concentration is gauged by the sensitiveness of the patient and the manner of local reaction. Occasionally severe reactions of periphlebitis are observed, even when one is under the impression that he has given a truly intravenous injection. If the first trial injection is borne well without an excessive local reaction, a stronger solution and multiple injections can be given without danger, and one may even treat both legs at the same time, which procedure considerably shortens the duration of treatment. It is best to give one or two injections and then to wait sufficiently long for the inflammatory reaction to subside, which usually takes four to five days. The duration of treatment varies with the individual case from three to four treatments for the less severe cases to ten to fifteen treatments in more extensive cases. From the point of time, this treatment does not compare favorably with surgical treatment, but it has the advantages of not confining the patient and absolute harmlessness.

It is dangerous to inject an inflamed vein or one that had a spontaneous inflammation, as in that case there may be severe reactions and instead of the desired aseptic phlebitis a septic phlebitis may cause all the dangers of general sepsis and embolism.

Blood Pressure.—R. S. Adams (*American Journal of Surgery,* Vol. XL, No. 1) asserts that the keeping of routine bloodpressure records in major surgery will convince anyone of the following facts:

1. Contrary to the general belief, surgery from the start, tends to lower the bloodpressure, and this depression in the average handicapped patient coming for operation, begins from five to twenty minutes prior to any other symptom indicative of the approaching shocked state. The use of several large abdominal packs, unless they are packed with great care, will cause a temporary drop in the systolic and diastolic pressure; and, if the packs are cold, the degree of drop is greater. Rough handling of the tissues and the intestines always markedly reduces the pressures and increases the pulse rate. Loss of blood, unless the quantity is very small, always lowers the pressures and afterwards increases the pulse rate.

2. All three general anesthetics now in use, ether, nitrous oxidoxygen, and ethyleneoxygen, cause a rise of bloodpressure, during the first fifteen minutes, the greatest rise occurring with nitrous oxid, the next with ethylene, and least with ether. But greater depression is seen with ether than obtains with the other two, and a deep ether anesthetic continued for over one hour in any patient, except the young adult of good cardiac compensation, nearly always causes a distinct drop in both systolic and diastolic pressures and a well recognized increase in the pulse rate.

It is true that ether is a cardiac stimulant, but this is not the case when the amount is used that is necessary to produce complete and absolute relaxation. Ethylene seems to produce more gradual changes in the pulse, respiration, systolic and diastolic pressure than nitrous oxid and is not as depressive as ether.

Spinal anesthesia nearly always produces such an extreme drop in bloodpressure that it is contraindicated in low pressure cases, and novocain, in some patients (particularly those of the nervous type) produces a distinct drop in pressure, and is not devoid of harm when used in large amounts as a local anesthetic.

3. Such extremely valuable information may be obtained by routine charting of the pulse, respiration and the systolic and diastolic pressures, that it is to be hoped that the procedure may be given a fair trial. If this is done, it will be agreed that this step, taken in conjunction with careful inspection of the patient as regards capillary circulation, depth of anesthesia, color, etc., will enable the patient to pass through the anesthetic and operation with the knowledge that everything possible has been done to safeguard this most perilous journey.

Successful Case of Embolectomy.—Geoffrey Jefferson (*British Medical Journal*, November 28, 1925) in reporting a case of successful embolectomy at the junction of the axillary and brachial arteries, describes the following technic:

No special instruments are required. Novocain infiltration is the anesthetic of choice. The incision of the vessel wall, removal of the clot, and suture of the outer coats follow the usual technic of blood-vessel surgery. Liquid paraffin or sodium citrate (one per cent.) may be used to prevent premature clotting in the wound. The only important advance in technic over earlier methods may be that in cases of embolism at the aortic bifurcation a distal approach is better than a direct. In these exposure of both femorals, which are then lightly clamped and opened, is followed by retrograde catheterization, the clot broken up, and removed through the openings in both vessels. This method is likely to give better results than a transperitoneal operation in a patient who is probably a bad surgical risk, owing to the presence of the heart disease which has furnished the material for the arterial blockage.

This method is not only one of absolute precision, but the condition of the patient may make it advisable, although much blood may be lost during the probing. Several cases are reported in which the thrombus has slipped away when the artery was exposed. A fresh incision should then be made lower down (for example, over the popliteal vessels). Wounds in arteries are easily sewn up, and one should not hesitate to make multiple incisions if occasion demands it.

Sclerosis of the Pulmonary Artery and Its Branches.—Hymen R. Miller (*Medical Clinics of North America*, November, 1925) points out the difference in the pathological picture between the socalled primary and secondary types of pulmonary atherosclerosis. In the former the lungs' finer radicles suffer, the larger vessels escaping practically intact, while in the secondary type the brunt of the impairment is borne by the medium and larger sized bloodvessels. A survey of the author's necropsy material emphasizes the significant rôle which mitral stenosis bears in the genesis of hypertension of the lesser circulation and eventual vessel sclerosis alteration. Mitral stenosis was found thirty-seven times at necropsy in patients who had no atherosclerosis of the greater or lesser systems. On the other hand, in eighteen cases of pulmonary vessel sclerosis and no general sclerosis, the mitral valve was markedly constricted in fifteen instances; only nine times was it stenosed in patients who had atherosclerosis of the general and lung arterial systems, but out of eighty cases, where there was marked general arteriosclerosis, but no pulmonary sclerosis, the mitral valve was stenosed in one instance only.

Clinically, we are concerned with a slow moving, but ever deepening cyanosis until the skin assumes almost a plum color. This intense, impressive cyanosis is strikingly disproportionate to a mild or even absent dyspnea. A high grade of polycythemia is not unlikely, but its nature differs in some important respects from true or absolute polycythemia. Pain is by no means constant. Its appearance may be paroxysmal, its character is ill defined, vaguely described as "deep within the lungs," but quite unmistakably unlike the typical angina anguish of coronary seizures. Hemoptysis also may be recurrent or entirely absent. In fact, an antecedent history of exacerbations and remissions of chest pain, lung bleeding, aggravated by cyanosis, asthma, etc., is not uncommon. Clubbing of the fingers and toes is unusual, indeed, some authors claim it does not occur. There is no body wasting, no cachexia, and no leukocytosis. The course of the condition is likely to be afebrile. When cardiac compensation breaks, edema, etc., may appear. The x ray and fluoroscopic examinations yield helpful data, *i. e.*, enlarged right heart, relatively small left heart, or enlargement of the conus, absence of pulmonary stasis, as found in cases of mitral stenosis. In general, the syndrome is fairly well defined, and its presence should suggest the possibility of sclerotic involvement of the lungs' bloodvessels; in the absence of heart or lung disorders this clinical picture may represent a socalled primary pulmonary vessel sclerosis.

The diagnosis of either form of lung vessel sclerosis, however, may be hazardous and difficult to separate, as indicated in the number of conditions that simulate it. The author is not prepared to say whether clinically one may distinguish clearly between primary and secondary sclerosis.

Finally, the bearing of infections upon the entire problem of pulmonary bloodvessel involvement has a particular interest for the clinician. Here belongs the consideration of such specific infections as syphilis, gonorrhea, variola, or the possible relationship of sclerosis of the pulmonary artery and its branches to clinical entities like Ayerza's disease, Raynaud's disease, or thromboangiitis obliterans (Puerger).

GENITOURINARY

The Preformed Sac and Oblique Inguinal Hernia.—W. Hughson (*Surgery, Gynecology and Obstetrics*, Vol. XLI, No. 5) reports that

1. In a series of cases in which the inguinal canal was opened on account of a relaxed ring and in which no clinical evidence of hernia was seen, in every instance a small persistent sac has been found.
2. Analysis of a group of cases shows that sixteen per cent. of individuals presenting hernia on one side eventually develop hernia on the opposite side.
3. It is felt that correlation of these facts lends further strong support to the preformed sac theory in regard to the etiology of all inguinal hernias.
4. A study of one hundred consecutive cases of both single and double herniotomies has shown that the double operation increases the incidence of postoperative pulmonary infections, but it does not increase the incidence of wound infection.
5. If any operative measures are used to repair the relaxed ring, a complete herniotomy should be performed.

Retroperitoneal Cysts.—H. W. Cave (*Surgery, Gynecology and Obstetrics*, Vol. XLI, No. 5) suggests that these cases are rare and each one should be reported, special attention being paid to the origin.

1. These cysts are rare and each case should be reported, special attention being paid to the origin.
2. Detailed macroscopic and microscopic descriptions of the pedicles or of the tissue in close proximity to its origin should be noted, as well as chemical and microscopical study of the contents.
3. The most interesting of these cysts originate in vestigial remains of the developing urogenital tract or in the lymphatic systems. Those lined with epithelium come from the former and those without a lining membrane, from the latter.
4. The diagnosis is difficult and symptomatology of but scant help.
5. Treatment is simple: enucleation in one or two stages, according to size of tumor and condition of patient, or marsupialization.
6. Prognosis is good. There is seldom a recurrence.

Urology in Europe Today.—C. P. Mathé (*International Journal of Medicine and Surgery*, Vol. XXXVIII, No. 11) records the varying methods and new developments employed among medical men in Paris, Germany and Austria, along urological lines. The "Constant d'Ambard," Ambard's formula for determining the functional ability of the kidney to excrete urea by comparing the urea in the blood to the urea in the urine, is used and advocated by the school of Prof. F. Legueu of Paris, while by that of Dr. Marion, also of Paris, it is criticized, and catheterization of both kidneys is employed instead, for purposes of examination.

There have been many advances in the treatment of bladder lesions. Professor Joseph has introduced chemotherapy in the treatment of inoperable tumors of the bladder. This consists of direct application of strong trichloacetic acid on the surface of the tumor. This reagent coagulates the tumor, reducing it in size, thereby ameliorating the symptoms. Sometimes he also combines this method with electrocautery of the tumor. Although the cystoscopic picture of malignant tumors of the bladder is usually characterized by central necrosis, he advises the removal of a small piece with rongeur forceps for diagnosis in doubtful cases. At the Necker Hospital, Dr. Flandrin is treating inoperable malignant bladder tumors by intravenous, intramuscular and paravesical injections of mesothorium bromide in conjunction with fulguration and the application of diathermy. In five cases the tumor entirely disappeared and in seven there was a marked diminution in its size, with amelioration of the symptoms.

Because of its resistance to treatment, pyelitis has been subjected to many new forms of therapy. In Professor Legueu's cystoscopic clinic at the Necker Hospital, chronic

pyelitis is treated by local injections of vaccine consisting of milliards of killed bacillus coli, bacilli of Friedlander, staphylococci and enterococci, or of the vaccine filtrate, at weekly intervals. Dr. Papin favors surgical drainage of the renal pelvis in resistant pyelitis cases. Through a small incision which is made through the most accessible portion of the pelvis, he passes a fine curved clamp into the pelvis, larger calyx and finally into a smaller calyx and pushes the renal parenchyma aside from within, emerging at the convex border. He then inserts a No. 20 or No. 23 French Malécot catheter through the renal parenchyma into the most dependent portion of the pelvis in the region of the lower calyx. He leaves this in place for seven to fourteen days, and makes a daily lavage with silver nitrate. Professor von Lichtenberg, at St. Hedwig's Hospital in Berlin, utilizes a similar operation for drainage, with the addition of decapsulation and nephropexy. There is no question that the elimination of stasis due to faulty drainage in persistently infected, ptosed kidneys, by nephropexy, does much to clear up chronic pyelitis. In Austria, in addition to renal lavage, pyelitis is being treated by three intravenous injections of 0.15 gm. of neosalvarsan at two-day intervals. Cylotropin, which contains forty per cent. urotropin, is also used. Three c. c. are injected intravenously every two days for acute pyelitis and cystitis.

Laboratory of Prostatic Hypertrophy.—R. C. Bryan (*International Journal of Medicine and Surgery,* June, 1925) urges the absolute necessity of frequent investigation of the urine and blood, to establish scientifically the ratio of the retained products in the circulation, for their varying percentage change daily, and it is only by an intimate appreciation of them and their significance, that justification for operation may be definitely and honestly determined.

Pathology of Hydronephrosis.—H. P. W. White (*British Journal of Surgery,* Vol. XIII, No. 50) outlines his study in the following manner:

1. Hydronephrosis with the dilatation beginning at the pelvoureteral junction is the commonest form of the disease. It occurs both as a congenital and an acquired condition.

2. Many cases of hydronephrosis have been reported in abnormally developed kidneys, but in what way these predispose to the disease is not known.

3. In a large proportion of the cases identified in fetal and early child life, and which are undoubtedly congenital, the dilatation is bilateral and often involves one ureter or both ureters, while in some fetal examples the lumen is completely obliterated.

4. In the great majority of cases of hydronephrosis the first manifestations of the disease are in adult life, most commonly between the ages of twenty and thirty years. In many of these the kidney is found to be in an extremely early stage of dilatation. It is therefore assumed that such cases represent the acquired form of the disease.

5. The earliest cases show narrowing of the ureter from chronic inflammation, and this appears to be the cause of the dilatation. In all cases there is an associated pyelitis, and some chronic interstitial nephritis.

6. Exacerbations of the existing pyelitis will explain the attacks of pain which come on without apparent cause in most cases of hydronephrosis. There is evidence of the infection either on cystoscopy or in the urine in a large proportion of cases during an attack of pain, which is often accompanied by increased frequency of micturition. There may be little or no evidence of infection after an attack has passed.

7. Chronic, or severe acute, inflammatory disease in any part of the body, chronic gastrointestinal derangement, and the pyelitis of pregnancy are common antecedents of hydronephrosis.

8. There is no conclusive evidence that renal mobility is ever a cause of hydronephrosis.

9. Traumatism is a rare cause, and results from the contraction of scar tissue in the wall of an injured ureter.

10. In drawing conclusions from the specimens I have put forward illustrating a vascular complication of hydronephrosis, I would call attention to the following facts:

a. They represent all the available examples demonstrating a vascular complication of a hydronephrosis, and throughout the whole series there is a complete uniformity in the mechanism producing this complication.

b. In nine of the eleven examples the vessel implicating the ureter is a normal inferior branch of one of the main renal vessels. In some instances it is the venous and not the arterial branch. In none of the specimens is the artery implicating the ureter aberrant in the sense that it enters the kidney through the cortex and not by way of the hilum.

c. It is therefore concluded that the process here described is the usual one which determines a vascular complication of the ureter in certain cases of hydronephrosis. The aberrancy of the vessel concerned is not necessary, in fact occurs infrequently, but offers the most favourable opportunity for compression of the ureter to occur when present.

d. It is obvious, however, that ultimately the ureter may be seriously compressed between the vessel and the distended pelvis in certain cases, and therefore some relief is likely to result from division of the constricting vessel.

Right Duodenal Hernia.—F. R. Brown (*British Journal of Surgery,* Vol. XIII, No. 50) reports a case successfully operated upon, and offers several suggestions as regards treatment.

Obstruction, when present, may be due to: 1, Constriction of the intestine by the orifice, although in most cases this is fortunately so large that strangulation does not occur. 2, Adhesions about the orifice of the sac. Thus Bernardbeig states that in his case the orifice was reduced in size by adhesions, which were broken down during the operation, and which played a very important part in the strangulation. 3, Axial twisting or volvulus of the intestine at the neck of the sac, as reported by several writers (Neumann, Carson, Bernardbeig, and others). The author suggests that obstruction may also occur outside the sac, and affect the bowel proximal to the orifice. The weight of the herniated intestine in its dependent sac will so drag on the root of the mesentery that constriction of the third part of the duodenum by the cord-like superior mesenteric artery is likely to result. This would give rise to the condition of duodenal ileus. In such an event, there would be no sudden increase in size of the tumor, since the efferent loop is not necessarily constricted.

Reduction, by traction on the afferent or efferent loop of intestine, is generally easy, and spontaneously relieves the obstruction, however caused. Should the orifice have to be enlarged, wounding of the superior mesenteric artery must be carefully avoided. The inferior margin only of the orifice may be incised.

If distention of the strangulated gut prevents reduction, the sac should be entered through an avascular space to the right of the superior mesenteric artery, and the bowel withdrawn, opened, and emptied, after which reduction through the orifice should be easily accomplished.

After reduction, closure of the neck of the sac should be attempted, if the condition of the patient permits, in order to prevent the possibility of recurrence. In at least two cases (Paton's and Mueller's), where this procedure was not carried out, it was found at postmortem examination that a considerable quantity of gut had re-entered the sacs.

Subphrenic Abscess.—A. O. Whipple (*American Journal of Surgery,* Vol. XL, No. 1) discusses the etiology, symptomatology, and differential diagnosis of this complication, and says, regarding treatment:

There is a measure which I am firmly convinced is of great value in preventing the development of a subphrenic abscess. This applies to cases of upper abdominal drainage such as is done for cholecystectomy or choledochostomy and consists of turning the patient over on the face two or three times a day after the first week of the operation. This has a very definite effect of emptying or draining the puddle of fluid that has a tendency to collect in the subhepatic space. Another precaution against this spread from a subhepatic collection to a subdiaphragmatic space is to leave drainage in long enough for a tract to be established. Considerable stress is laid by most writers on the subject upon early incision and drainage of the subphrenic abscess. This is undoubtedly wise once the diagnosis of abscess is established; but early needling and too early exploring of the subdiaphragmatic area may do considerable harm and may result in a subphrenic infection where none had existed. Daily x ray and physical examination with notes for comparison will usually determine in three or four days whether an abscess is really present.

As a rule the tenth rib in the midaxillary line is the best approach. Under paravertebral novocain injection going two rib spaces above and below the tenth rib will give much

better anesthesia than the local over the line of incision alone. Either the intercostal incision or removal of a segment of rib will give good exposure and drainage, provided the incision is long enough. The mistake too frequently made is too short an incision, too small a segement of rib removed. The newer, electrically lighted, illuminated retractors are of great help in inspecting the size and site of the abscess. Care in avoiding the pleura by pushing it up by gauze dissection will prevent much trouble.

Two large soft rubber tubes, so arranged that they can be connected to bottle drainage for irrigation purposes afford the best drainage. The wound edges do well with dichloramine—or iodoform—gauze packing. Little or no suturing is necessary. Within one or two days we begin dakinization if the abscess wall is well formed and has no peritoneal communications.

Inguinal Hernia.—R. H. Russell (*Surgery, Gynecology and Obstetrics,* Vol. XLI, No. 5) states that in saccular hernia removal of the sac will cure the hernia. His operative procedure after exposure of the canal by incision of the external oblique and location of the sac, reads as follows:

1. Seize the sac in a pressure forceps and pull it forcibly out; strip the structures of the cord completely away from the sac and abdominal peritoneum, and this involves working deeply in the abdomen; free the neck of the sac by sweeping the finger all around it.

2. Twist the sac tightly up until practically you can twist no more, pulling forcibly upon it all the time. This will insure that the entire sac will be torsioned up to the point where it comes off from the abdominal peritoneum, and it is at this point that the ligature must be applied.

3. Do not transfix with a needle; apply a "crusher" of some sort to the spot where the ligature is to go; below the crusher throw the ligature (catgut always, never silk) which will slip into the crush as the instrument is taken off.

4. Nothing more will remain to be done, except to repair the incision in the external oblique. Personally I prefer to do this by merely including it in one or two of the stitches employed for closure of the outer wound.

I attach great value to the tight torsioning and forcible pulling on the sac; also to nontransfixion, and the use of catgut always as a ligature.

ANESTHESIA

Ethylene Oxygen.—J. S Lundy (*American Journal of Surgery,* Vol. XXXIX, No. 10) describes, for the benefit of those who are inexperienced in gas anesthesia, the method of administration of ethylene oxygen. This anesthetic is indicated in nearly all types of ordinary minor surgical cases. Its principal indication, however, is the weak, debilitated patient. In operations requiring a cautery or similar apparatus, its use is contraindicated. Neither will it suffice, combined with oxygen, for laparotomy in the presence of acute peritonitis, and it frequently fails in operations on the gallbladder. It does not afford the profound relaxation that can be obtained with ether.

The signs and symptoms of ethylene oxygen anesthesia are outlined in tabulated form, various adjuvants are suggested, and the method of administration, including induction and optimal saturation, and the operative period, is set forth in detail.

Ethylene Anesthesia.—C. L. Hewer (*American Journal of Surgery,* Vol. XXXIX, No. 10) presents the results of one hundred and twenty administrations of ethylene as follows: The operations included abdominal exploration, amputation of the breast, excision of cysts, glands, ganglia and polypi, incision and drainage of abscesses, suture of tendons, circumcision, tonsillectomy, and dental extractions. The total time of anesthesia varied between two and fifty-eight minutes, while the age of the patients was from two to sixty-two years.

The average time for the induction of anesthesia was one minute fifty seconds. No case gave rise to any anxiety during operation. Anesthesia was completely satisfactory in one hundred and ten cases with ethylene or ethylene oxygen only. In five of the remaining patients a little ether had to be added to secure the necessary relaxation. The rest of the unsatisfactory cases were all dental extractions which exceeded the estimated time, a nasal apparatus not being available. If this could have been used there is no reason to suppose that the anesthesia could not have been extended to enable all the extractions to be completed. The "single-dose" method usually gives about one and one-quarter minutes anesthesia, which is longer than with a "straight gas" and rather shorter than with closed ethyl chlorid. The noticeable lack of aftereffects constitutes the chief advantage of ethylene anesthesia.

These results agree substantially with the reports of large numbers of cases anesthetized with ethylene in America, and appear to show that this gas has certain advantages over the other anesthetics at present in use, especially for minor operations taking a moderate time and which requires more than nitrous oxid.

Scopolamine Morphine Seminarcosis.—O. H. Schwarz and O. S. Krebs (*American Journal of Surgery,* Vol. XXXIX, No. 10) reports on the use of seminarcosis in the Barnes Hospital, St. Louis. It is employed in ward service only in the cases in which no abnormality presents itself at the beginning of labor. Thus all cases in which the fetus is known to be dead are excluded, as well as those of moderately contracted pelvis, where prolonged labor and an abnormal mechanism might be expected. To such, nitrous oxide is administered as desired.

Seminarcosis is used chiefly as a first stage measure, but its effect in most instances lasts well into the second stage up to the time when the presenting part becomes visible, when one of the common general anesthetics is employed. Our method and plan of procedure has been fully described in our previous publications, and usually consists of two injections of 1/133 grs. of scopolamin repeated in forty-five minutes, the first injection being combined with 1/6 gr. of morphin. The injections are given subcutaneously. This procedure is very important as it is not desirable to get the scopolamin to act too quickly. Subsequent injections are given, 1/266 gr., at intervals, as indicated by the course of labor and condition of the patient.

In the primiparas the procedure is usually started when there is about two finger breadths dilatation and the patient is definitely complaining of pain. In the multiparas it may be started as soon as active labor begins and the patient complains of pain. It can be used in the multipara with advantage in cases where it is obvious that labor will not terminate within three hours. When a multipara enters the hospital in active labor and it is apparent that her labor is to be terminated comparatively soon, we prefer to use nitrous oxid, and we presume that ethylene would especially be applicable for such cases, although we have had no experience with its use.

We know of no method, which by such a simple procedure as two or three hypodermic injections can result in such complete amnesia over a period of such considerable time, that enables at least eighty to eighty-five per cent. of these cases to go through labor without its recollection. Fetal asphyxia is not increased, although an occasional child is born in a state of oligopnea, from which they usually promptly recover on the slightest stimulation.

The disadvantages of the method are chiefly from the standpoint of the attendants. Someone must be constantly with the patient, particularly the one who is supervising the injections. The other disadvantage is the not infrequent restlessness and occasional excitability of the patient. This is, however, by no means striking. It has no effect on the patient herself but at times is quite taxing to the attendant. If this restlessness and excitability which we occasionally see, can be eliminated, the method could soon be pronounced ideal.

Gas Anesthesia.—A. Goldman and J. D. Goldman (*American Journal of Surgery.* Vol. XL, No. 1) find that acetylene oxygen meets the demands of extraction and oral surgery more fully than other methods of anesthetic. With nitrous oxid acetylene oxygen the oxygen content of the blood is normal throughout the anesthesia. In answer to the question, "What advantages has acetylene plus nitrous oxid plus ethylene with oxygen over acetylene alone with oxygen?" the writers assert that here the principle of synergism is seen clinically to apply.

Anesthesia is produced through the reduction of the oxygen supply sufficient to affect consciousness, pain apperception and pain perception. The oxygen must be in sufficient quantity for the respiratory and cardiac functions to continue. With ethylene the oxygen supply varies from seven

to twelve per cent. With acetylene the oxygen supply of the inspired gasses is never less than thirty per cent. and usually above forty per cent. The more soluble a gas the more reduction of the oxidative processes with an equal percentage of oxygen. Ethylene is more soluble in blood than is nitrous oxid. We may, therefore, expect less reduction of the oxidative processes when seven per cent. oxygen is inspired with ninety-three per cent. nitrous oxid than when seven per cent. oxygen is inspired with ninety-three per cent. ethylene. Acetylene is still more soluble than is ethylene.

SURGERY

Osteitis Fibrosa and Bone Syphilis.—S. E. Wilhelm (*Surgery, Gynecology and Obstetrics,* Vol. XLI, No. 5) draws the following conclusions from his anatomical and röntgenological study of the subject:

1. There are gross anatomical and clinical resemblances between the hyperostotic form of syphilis of the long bones and osteitis fibrosa, both the senile hyperostotic porotic form and the juvenile endosteal type. Coarser gross morphological similarities, such as deformities, elongation and bowing, and especially, the sabre blade form of tibia, are found in the affected bones of both diseases.

2. Despite these external similarities we are dealing, especially in regard to their histogenesis, with two fundamentally different diseases. The essential differences in their nature express themselves in the individual anatomico pathological characteristics of the affected bones, and also in their röntgen pictures.

3. Characteristic of hyperostotic syphilis are: (a) the marked, often tremendous, participation of the periosteum; (b) the more or less advanced narrowing and obliteration of the marrow cavity; (c) the sclerotic or finely porous quality of the newly built bone tissue. The meshes or pores particularly in the röntgen pictures seem to be directed lengthwise, parallel to the long axis of the diaphysis.

The sabre blade or sabre sheath form of tibia in syphilis may be due purely to a periosteal new formation of bone, i. e., a pseudobowing; or to an osteitic rebuilding and elongation, resulting in a true bowing.

4. Characteristic of the senile hyperostotic-porotic form of osteitis fibrosa, Paget's disease, are: (a) The absence of periosteal participation; (b) the very great widening of the marrow cavity, even into the epiphyses; (c) the frequent lengthwise splitting up of the compacta into lamellas. The sabre blade tibia of Paget's disease is the result of the rebuilding and elongation of the bone, i. e., a true bowing.

5. In the juvenile endosteal hyperostotic-porotic form, there also is a complete absence of periosteal involvement. Only these latter cases may be difficult to distinguish röntgenologically from congenital bone syphilis.

The occurrence of more or less well formed cysts, or of single, circumscribed, dense foci accompanying a diffusely spreading osteitic new bone formation, are diagnostic points in favor of osteitis fibrosa, as against lues. In the remaining still doubtful cases, additional clinical methods should be employed to arrive at a diagnosis.

Osteitis Deformans.—R. L. Knaggs (*British Journal of Surgery,* Vol. XIII, No. 50) approaches this disease from the point of view of its relation to osteitis fibrosa and osteomalacia, and summarizes his argument as follows:

1. Certain diseases of the bones owe their origin to the action of toxins— probably those of metabolic or intestinal origin.

2. Predisposing to their development an idiosyncratic susceptibility on the part of those who suffer from them may be assumed.

3. The ability of the bones to resist toxic influence is a factor of great importance.

4. The relative intensity of that resistance can be roughly gauged by the extent and character of the reaction excited in the soft tissues of the affected bones.

5. If the vitality is good, the resistance opposed to the toxins may ward off harmful effects till the constitutional strength is reduced by age and disease. The reaction under these circumstances is strong, and the resulting affection takes the form of *osteitis deformans.*

6. On the other hand, if vitality is feeble the disease appears earlier—in childhood, adolescence, or early manhood. The reaction is fair, but not so vigorous as in osteitis deformans. The form the disease then assumes is that of *osteitis fibrosa.*

7. Lastly, when owing to the severe depression of the patient's vitality, usually by untoward circumstances, the power to react is absent *osteomalacia* develops.

Apophysitis of the Os Calcis.—P. Lewin (*Surgery, Gynecology and Obstetrics,* Vol. XLI, No. 5) defines this complication as an inflammation of the caplike epiphysis of the posterior portion of the heel bone. It is a fairly common condition occurring usually in boys between the ages of nine and thirteen years. The probable etiology is concerned with two factors: local external and especially internal trauma and local circulatory disturbances affecting the epiphysis during a critical period in its growth and development. The treatment consists of immobilization and relief from weight bearing plus general hygienic considerations. The prognosis is excellent. The condition is analogous to Legg's disease, Koehler's tarsal scaphoiditis, Scheuermann's vertebral epiphysitis, Freiberg's infraction of the metatarsal head, but especially to Osgood's tibial epiphysitis.

More röntgenological observations must be made on the normal or symptomless heels of children between six and sixteen before accurate statements can be made about pathological heels. It is evident that there are marked "normal" variations.

Developmental Anomalies of the Patella.—J. D. Adams and R. D. Leonard (*Surgery, Gynecology and Obstetrics,* Vol. XLI, No. 5) point out that the danger in mistaking congenital anomalies for fracture is more common than generally supposed. The differential diagnosis between the two can easily be made however by an x ray film. Congenital deformities are usually bilateral. The adjacent surfaces of the bones are smooth and consist of cortical bone. The congenital anomalies are located in the outer and upper quadrant, which is a rare location for fracture. The absence of a typical clinical history and the symptoms usually associated with fracture should make the examiner suspicious that he is dealing with a congenital anomaly.

The Relation of Chronic Foci of Infection to Kidney Infection.—Russell L. Haden (*American Journal of the Medical Sciences,* March, 1925) says that pyogenic kidney infection is almost always of hematogenous origin. The pathological picture is variable and cannot be determined from the clinical symptoms. The socalled pyelitis in the absence of obstruction is almost always a pyelonephritis. The colon bacillus is probably seldom the primary invader except possibly in cases of lower urinary tract obstruction. The infecting agent is usually a streptococcus or staphylococcus which produces lesions by reason, either of great virulence or an especial affinity for kidney tissue acquired in a chronic focus. In a great majority of cases of chronic pyogenic kidney infection the organism is fed into the blood stream from chronic foci of infection. Six cases are reported in which kidney lesions similar to those from which the patient suffered were produced in animals by the intravenous injection of organisms recovered from infected teeth. The need for the proper consideration of chronic focal infection in treating such cases of kidney infection is apparent.

Postrectal Tumors.—C. J. Drueck (*American Journal of Surgery,* Vol. XXXIX, No. 10) writes of his subject, briefly, as follows:

Treatment of Dermoids: If suspended by a pedicle the attachment should be transfixed as its base and securely tied, and the dermoid cut away. If deeply attached or covered with other tissues they must be enucleated.

Treatment of Teratoma of Embryoma: Through an erroneous diagnosis the patient may be submitted to an exploratory laparotomy, the abdomen being opened by a median incision. The tumor is then found to be retroperitoneal and behind all the pelvic viscera. By this method of approach the operator must work in a deep cavity where the control of hemorrhage is difficult if not impossible. Attack by the peritioneal route is likewise impracticable because the rectum and ureter have been pushed down by the growth. Sacral resection is the only successful way to reach these growths but even this posterior route is too grave an operation to supplement a previous exploration.

The patient is prepared in the right lateroprone position, the hips being well raised and the thighs flexed. A Kraske incision, beginning just posterior to the anus, is carried up in the median line to the upper limit of the coccyx and then follows along the left edge of the sacrum. This incision is carried down to the bone and the wound is widened to the right and left, lifting off the gluteal muscles until the sacrum and sacrosciatic ligament are exposed.

The third sacral nerves are to be identified and the sacrum divided below them. The central canal of the sacrum is not to be opened. The attachment of the sacrosciatic ligament to the coccyx is severed and the lower sacrum is also freed by blunt dissection. The amputation is best done with a Gigli wire saw. The use of chisel and mallet here causes shock.

As the sacrum is lifted off the tumors are often in plain view and after all bleeding has been arrested the growth may be leisurely studied and can usually be removed without disturbing the pelvic viscera or opening the peritoneal cavity.

Bronchoscopic Treatment of Lung Abscess.—M. C. Myerson (*Surgery, Gynecology and Obstetrics,* Vol. XLI, No. 5) recommends a more earnest trial of bronchoscopy in nonexpectant treatment of suppurative lung disease. This procedure which is done without anesthesia in children, and with a small amount of local anesthetic in adults, is free from injury of any kind to the individual when performed by skilled endoscopists. When properly performed, it is not as formidable as the profession has been led to believe. Today, in the hands of qualified workers, this treatment has no mortality, and should be considered before surgery is undertaken as surgery in most cases is deforming, and is not without danger to life.

Trauma and Malignant Tumors.—J. Ewing (*American Journal of Surgery,* Vol. XL. No. 2) cites the five following conditions as those essential to the acceptance of trauma as the cause of a tumor:

1. The authenticity and sufficient severity of the trauma.
2. Previous integrity of the wounded part.
3. The identity of the injured area with that giving origin to the tumor.
4. The tumor must be of a type that could conceivably result from trauma.
5. There must be a proper time interval between the receipt of the injury and the appearance of the tumor.

This review of the data required to establish the traumatic origin of a malignant, tumor emphasizes the complexity of the problem. It is obvious that such data are very seldom presented, and many of them are difficult to obtain. Some of them are essentially matters of interpretation rather than of definite determination. Nevertheless, without them one cannot assert that a tumor is of traumatic origin. The traumatic theory runs against too many general objection to permit its uncritical acceptance. Moreover the effective exciting factors of most of the common forms of cancer are sufficiently well known to exclude trauma. Hence it is a safe conclusion that trauma rarely produces cancer de novo. More often it brings to light a previously existing cancer or excites a miniature cancer or possibly a pre-cancerous lesion to more rapid growth.

Dermatolysis.—Herman Goodman and Eugene Traub (*Surgery, Gynecology, and Obstetrics,* Vol. XLI, No. 5) state that dermatolysis is regarded as a rare disease. It is variously known as Loosenski; cutis laxa; cutis pendula; Pachydermatocele; and chalazoderma. The partial or circumscribed form of dermatolysis is characterized by areas of hypertrophy and looseness of the skin and subcutaneous tissues. The affected area of skin may hang in loose folds or be sufficiently elastic to allow of stretching. The appearance of the surface of the integument may be normal, hyperpigmented, with dilated and gaping follicles or comedones. The skin is usually thickened, but exceptionally it is thinner than normal. On palpation, one gets a doughy or velvety soft feel of a greasy, uneven surface. The sensation may be unaffected or hypersensitive. There are no subjective symptoms. Although any part of the body may be affected, the locations most frequently involved are the face, especially the eyelids; the neck, the abdomen; and the genital region. The condition is somewhat progressive. After reaching a certain stage of development it may remain stationary.

The etiology is unknown. In certain instances the condition is congenital, in others hereditary (several generations); but usually it as acquired. The starting point may be the site of former trauma, and the vague term of "trophoneurosis" has been applied to the causation.

The diseases which may be confused with dermatolysis include diffuse dermatolysis or cutis hyperelastica. The "elastic skin" or indiarubber man of the circus side show is an excellent example of this form of dermatolysis. Here the integument is generally loosely attached to the subcutaneous tissue, and has the property of great distensibility, occurring normally in the young of certain animals, as kittens. Diffuse dermatolysis has been studied by a number of observers.

Dermatolysis must not be confused with the relaxation of the skin and subcutaneous tissues encountered in senility and after pregnancy. In both of these, hypertrophy of the constituents of the skin is lacking. Nævi and sebaceous cysts are readily distinguished by the absence of the features of true partial or circumscribed dermatolysis. The relaxation and hanging-in folds of the skin are features of pseudoxanthoma elasticum, but associated papules and plaques are absent in dermatolysis.

Postoperative Adhesions.—L. Schönbauer (*Wiener klinische Wochenschrift,* August 21, 1924) maintains that shown that bacteria alone are not sufficient to produce postoperative adhesions. The bands of adhesions are formed only when tryptic ferments reach the peritoneum at the same time. The formation of adhesions may be avoided by preliminary treatment with trypsin. The author intends to make an antitryptic serum, to be used in operations.

Aneurysms of Scarpa's Triangle.—R. W. McNealy and J. L. Spivack (*Surgery, Gynecology and Obstetrics,* Vol. XLI, No. 6) find this complication comparatively common. Arteriovenous aneurysms outnumber the simple variety, however. Arauma and lues are the important etiological factors.

In most cases provisional ligature of artery and vein followed by permanent quadruple ligation with excision or plication of sac will produce excellent results.

Surgery of Uterus and Adnexa.—E. H. Pool and E. M. Hawks (*Surgery, Gynecology and Obstetrics,* Vol. XLI, No. 6) print their results of ten years' experience with surgery of the uterus and adnexa, finding that conservative treatment of follicular and corpus luteum cysts is satisfactory. Irrespective of the type of cyst, it is advisable to remove both ovaries when true epithelial papillas are found on one side.

Proved Tuberculosis of the Pleura.—W. S. Lemon (*Surgery, Gynecology and Obstetrics,* Vol. XLI, No. 6) records thirty cases which bring him to conclude that it would seem wise to regard all cases of serous effusion as tuberculous, and to bear in mind that a great deal of harm can be done by hasty or ill considered treatment, and that a large percentage of all cases of empyema, especially if not preceded by pneumonia or sepsis, are also tuberculous.

In planning methods of treatment, great care should be exercised in the preliminary evaluation of the history, in the examination of the aspirated fluid, and in the consideration of implications involved in cases of sterile exudate. Any lack of such care and consideration results in failure to conduct treatment intelligently, and reduces the patient to a condition of chronic invalidism. Should the patient finally recover from the subsequent necessary operative procedures the end result, although satisfactory, is not a triumph but rather a test of his own vitality.

Malignancy of the Breast.—L. Frank (*American Journal of Surgery,* Vol. XXXIX. No. 10) asserts that early diagnosis with extensive radical operation, bearing in mind the avenues of dissemination, offers the best hope of permanent cure.

Postoperative "rheumatism," neuritis, etc., should be viewed as probably due to metastasis until proven to be otherwise.

Removal of a section of the tumor for diagnostic purposes should always be done with a cawtery knife and all breasts removed as carcinomatous should be examined postoperatively to confirm this diagnosis.

Certain types of chronic mastitis may be definitely looked upon as precancerous in character.

The röntgen ray used postoperatively is of definite value

in the prevention of recurrences. Its preoperative use for blocking the lymphatics is of very doubtful value.

Dislocation of Astragalus.—W. L. Sneed (*Journal of Bone and Joint Surgery,* April, 1925) maintains that in all severe dislocations of the astragalus the blood supply of the bone is interrupted, perhaps temporarily destroyed. There is no main nutrient artery to this bone. It is supplied by numerous small blood vessels, which cannot be stretched to the degree necessary for dislocation without rupture. In severe dislocations of the astragalus this bone may be replaced in normal position and a good functioning foot may be hoped for.

PEDIATRICS

Applicability of Various Diagnostic Tuberculin Tests.—After comparing the various diagnostic tuberculin tests, Herman Czickeli and Richard Haller (*Wiener klinische Wochenschrift,* January 29, 1925) recommended the Moro concentrated percutaneous reaction, as modified by Hamburger. Percutaneous reactions are well borne both by children and by their parents. Another advantage of this reaction is the fact that it can still be read even after five to seven days. It is positive in 80 to 90 per cent of cases.

The technic is as follows: The test is made and may be repeated in a week if necessary. If it results negatively, 0.1 mg. of tuberculin is again injected on the second day, and if this is negative, 1.0 mg. is injected subcutaneously on the next day. If all the tests are negative within three days, the presence of tuberculosis is unlikely in ninety nine per cent of the cases. The entire procedure may be repeated after one week if necessary.

Wheal Formation in Infants and Children.—J. D. Pilcher (*American Journal of Diseases of Children,* January, 1926) discusses wheal formation in infants and children in edema, cretinism, scleredema, sclerema, nephritis, cardiac disease, severe prostration and tuberculin positive subjects. In infants with rickets or spasmophilia low serum calcium and phosphorus, down to half the normal quantity, have no influence on the permeability of the minute vessels of the skin, as measured by the codeine wheal reaction.

Cervical Adenitis.—R. Franklin Carter in discussing cervical adenitis (*Archives of Pediatrics,* October, 1925) believes the point should be emphasized that, when the problem is to be treated as one of infection, the nodes, which fulfill the purpose of filtering microorganisms out of the system, are not to be regarded as offending agents and removed indiscriminately: rather, the source of infection often elusive on first investigation is to be sought until located. Attention to the portal of entry frequently obviates the necessity for surgical reatment of the nodes. If, however, simply restoration of function is desired Dr. Carter favors incisions of a quarter inch in length preferably where the neck creases naturally and at the margin of the superficial abscess so that the skin may not attach to the deep fascia and, together with destruction of fat leave an unsightly scar. The article is well illustrated by pictures of types of inflammation and scars, and diagrams in explanation of the text.

Prevention of Orchitis in Mumps by Injection of Convalescent Serum.—V. de Lavergne and P. Florentin (*Bulletin de l'Académie de médecine,* March 31, 1925) tested this procedure in 113 cases. The blood was collected from the fifteenth to the twenty-fith day in uncomplicated mumps cases or upon restoration of the general condition in cases with orchitis. The usual Wassermann test, addition of phenol and heating to 56° C were carried out. The dosage preferred is twenty mils in two injections of fifteen and five mils, respectively, though the earlier cases received only ten or fifteen mils. Among 107 untreated cases, twenty-five were complicated with orchitis and nine with clinical meningeal reactions, whereas among the 113 treated cases only five had orchitis and two meningeal reactions. Furthermore, the last twenty-eight cases treated, all of which received twenty mils of serum, were all free of orchitis. The serum used in mumps should be a mixture of that from several cases and should be given in generous amounts, for the following reasons: Convalescence does not set in, as in measles, at an easily ascertainable time. It is possible for orchitis to appear as late as the twentieth to the forty-fifth day, showing that even at an advance period in convalescence immunity may not yet be sufficient to extinguish the activity of the virus. In one instance blood was collected from a patient on the eighteenth day of convalescence and on the twentieth day he developed orchitis; the serum obtained from the patient was doubtless altogether lasting in preventative value. Again, relapses of mumps may occur, as was noted in two of the authors' patients; in such cases likewise the serum is presumed to be valuless.

The Zed Reaction in Inanition.—John Zahorsky (*Medical Clinics of North America,* July, 1925) proposes the name Zed reaction to a singular group of symptoms which appear in the majority of cases of partial or complete starvation whenever the starved condition is relieved, as is seen most strikingly in cases of pyloric stenosis of young infants a short time after the pyloric stenosis is opened; but the symptoms also occur in other forms of inanition, e.g., after prolonged feeding with cereal decoctions and other foods which are deficient in protein content and caloric value. It is a common manifestation in marasmus (athrepsia). The name Zed is an old name for the letter Z. Here it means nothing, except that it designates a final reaction before recovery.

The Zed reaction is characterized by a slight gain in weight, an elevation of temperature, and the appearance of watery stools, which contain a large number of cells. The reaction may be slight; it may be so severe as to end in death. It is an inflammatory condition of the intestinal mucosa occurring in infants previously starved after proper feeding is instituted. Microscopically, the stools reveal a great discharge of cells—columnar epithelium, lymphocytes, leucocytes, and lymphoid cells. These fill the fluid part of the stool or are embedded in shreds of mucus. Many times clumps of degenerated leucocytes (pus cells) were observed. The stool also reveals undigested curds or flakes suspended in a watery fluid. The color varies from yellow to green. Gradually this consistency increases and a normal stool is found after several days. In severe cases the fluid nature of the stool may persist for two weeks, with frequent relapses after recovery.

The cause of the Zed reaction is a cleansing process following a severe mucosal contamination. The severity of the reaction depends on many factors, the chief of which are the extent of the contamination, the number and the virulence of the bacteria which have penetrated the columnar lining, and the resistance of the infant. Too much undigested food by its own fermentative product will, of course, aggravate the symptoms.

Whenever the Zed reaction appears, do not assume that the infant does not tolerate the food and immediately place it on a starvation diet, but continue to feed the baby a maintenance or an optimum ration with plenty of protein until this intestinal inflammation subsides. Many a baby is starved to death the assumption that it is intolerant to food, when, as a matter of fact, it merely is cleaning up a mucosal contamination. The mucopurulent discharge can be disregarded, as it must go on until the intestines are cleaned. Check the peristalsis by medication (paregoric, bismuth, tannin), but do not starve the baby. It is only by feeding the child and keeping up an increasing blood volume that the intestines can be restored to health.

Surgical Treatment of General Peritonitis.—A. C. Arnet (*International Journal of Medicine and Surgtry,* Vol. XXXVIII, No. 11) outlines his routine method as follows: Local anesthesia or gas oxygen, quick operation with a minimum of trauma and removal of cause, free drainage, morphin regularly until peristalis is reestablished, hot dressings, hypodermoclysis and the absolute avoidance of all cathartics, constitute our routine method in the treatment of these cases.

A split muscle transverse incision is used in preference to the more common varieties as the latter almost always develop incisional hernia following drainage. The split muscle transverse is made transversely at the level of iliac crest, extending from the iliac crest internally to a point slightly beyond the outer margin of the rectus muscle. It is carried down through the skin, fat transversalis fascia, internal oblique muscle and peritoneum. The rectus is not cut, that portion of the incision extending over the rectus being carried in depth through the muscle sheath only. Two of these incisions are made, one on either side.

NEW YORK, WEDNESDAY, AUGUST 18, 1926

Medicolegal Notes.

PHYSICIAN MUST FILE REPORT UNDER NEW YORK WORKMEN'S COMPENSATION ACT

The New York Appellate Division, La Duca v. U. S. Light & Heat Corporation, 212 N. Y. Supp., 240, reversed an award on the ground that the physician who rendered the medical services for which the award was made did not comply with the provisions of section 13 of the Workmen's Compensation Law as to filing a report of the injury and treatment on the form prescribed by law.

PRIVILEGED COMMUNICATIONS—PENNSYLVANIA STATUTE

An assured in his application for life insurance stated that he had never had convulsions, an answer material to the risk. A physician who had attended the assured was asked whether he had treated him for epilepsy or convulsions. The trial court excluded the question on the ground that the witness had indicated to the court that the specific disease from which assured was suffering was a loathsome one of which epilepsy and convulsions were only symptoms, basing the ruling on the statute as to privileged communications which would tend to blacken the patient's character. Pa. Stat. 1920, Sec. 21860. The Pennsylvania Supreme Court holds, Skruch v. Metropolitan Life Ins. Co., 284 Pa., 299, 131 Atl. 186, that if the defendant, having received an affirmative answer to the question propounded, had then attempted to follow it up by an inquiry which if answered would have shown that the convulsions and epilepsy were symptoms of a loathsome disease the act would have applied, and an objection to the later inquiry would have been properly sustained; but no such question was asked.

PROCEDURE UNDER NEW JERSEY ACT FOR PENALTY FOR PRACTICING WITHOUT LICENSE

The New Jersey Supreme Court holds, State Board of Medical Examiners v. Buettel, 131 Atl. 89, that the Act May 22, 1894 (P. L., page 454), as amended by Act April 6, 1921 (P. L., p. 702), authorizing an action by the state board of medical examiners to recover a penalty for practicing without a license is valid, and that the Legislature clearly intended that the proceeding should be heard in summary manner without a jury, although the steps in the proceeding are not set forth in the act. Where these are left open in the act, it will be presumed that the course of procedure in the trial court was intended.

PROOF OF POSSESSION OF LICENSE TO PRACTICE

The South Carolina Supreme Court holds, State v. Deadwyler, 130 S. E., 332, that, in a prosecution under Civ. Code, 1922, Sec. 2415, for practicing medicine without a license, although it is necessary for the state to allege that the defendant did not have a license, the burden is on the defendant and not on the state to prove, after the act of practicing has been proven, that he had a license. The defendant knew whether he had a license or not and could have produced it, and he offered no testimony. It was also held that it was competent for a member of the state board of medical examiners to testify that he knew of his own knowledge whether the defendant had passed the board of examiners and received a license, as against the objection that this was not the best evidence.

CIRCUMSTANCES SHOWING LIABILITY FOR MEDICAL SERVICES

In an action in the Georgia courts by a physician for the value of professional services rendered by him, the Georgia Court of Appeals holds, Becker v. Humphries, 130 S. E. 379, that an allegation that the plaintiff had been licensed to practice medicine in the state of Georgia was unnecessary where it appeared that the physician was located in the state of Florida and neither the account nor the petition disclosed where the services were rendered. Moreover, the court said, it seems to be the rule that in such an action it is sufficient to allege that the plaintiff is a physician, "that he was employed as such, that he rendered the services alleged, and that the reasonable value thereof was the amount sued for. By the weight of authority, it was not necessary that the petition should go further and show that he had a license to practice according to the legal requirements of the state in which the services were performed. Of course, if it appears that the physician was practicing without a license, in violation of statute, he cannot recover. But this would ordinarily be a matter of defense. . . . The copy of the account, which was expressly made a part of the petition, shows that the plaintiff was an M. D. and this court will take judicial cognizance that this abbreviation imports prima facie that the plaintiff was a physician."

The defendant further contended that it appeared from the petition that the plaintiff was claiming a liability against the defendant for professional services rendered to a third person, and that the plaintiff could not recover therefor without showing an express agreement by the defendant to pay for such services. Even if so, the court said, the petition was sufficient to withstand the attack of a mere general demurrer based upon this ground. It alleged that the defendant was indebted on the account, and that the services were rendered "on order," the reasonable inference being that the order was that of the defendant. Furthermore, suit upon an open account may be sustained though the evidence shows an express agreement, where it is proved that the plaintiff has fully performed his part of the agreement, and nothing remains to be done except for the other party to make payment. In the nature of the action it was not necessary for the plaintiff to allege an express agreement by the defendant to pay, irrespective of whether such agreement should be proved, to entitle him to recover.

In the present case the patient was living on the defendant's farm, but there was no such relation between them as would raise a legal obligation on the defendant's part to procure and pay for the physician's services. There was, however, a continuation of these services upon repeated requests by the defendant, and, in most instances, with the defendant present assuming charge of what was done. Another physician had been in charge of the case, but had to go away, and thereupon the defendant brought in the plaintiff. Subsequently, when the patient was seen to be in a bad condition, the defendant told the plaintiff to get a nurse, which was done, and defendant paid for her services.

The court said that the preponderance of authority is to the effect that a mere request by one person to a physician to render services to another, to whom the person making the request is under no obligation to supply such services, will not raise an implied promise in favor of the physician to pay for the services when rendered. The true rule in a case of this sort seems to be that the plaintiff could not recover without showing affirmatively, either that the services were rendered under an express promise on the part of the defendant to pay therefor, or that the surrounding circumstances were such as plainly to indicate that it was the intention of both parties that the defendant would be liable. It was held that, while the evidence failed to show an express promise, the other circumstances, as disclosed by the evidence, were sufficient to authorize an inference of an intention by the parties, at the time, that the services were to be furnished on the defendant's credit, and that a finding for the defendant was warranted.

The Present Position of the Theories of Vision and Color Vision

F. W. EDRIDGE-GREEN, C.B.E., M.D., F.R.C.S., L.R.C.P.
London

The subjects of vision and color vision are at the present time in a state of chaos. This is due to several causes, chief of which are, the extreme difficulty of the subject which embraces so many branches of science, that few are in a position to give an opinion; the great eminence of the authors of the older theories; the fanatical advocacy of supporters of these theories, many of whom do not understand them, and the continued repetition of misstatements. All the facts relating to these subjects need careful revision with the most minute accuracy of apparatus and method.

ANATOMICAL BASIS OF VISION AND COLOR VISION

The images of external objects are formed upon the outer layer of the retina, the layer which is furthest away from the front of the eye, so that light has to pass through all the other layers before it reaches the sensitive portion. This sensitive layer consists of two elements, which are called, respectively, on account of their shape, the rods and cones. There is a little dip in the centre of the retina, the fovea, and it is the region of most distinct vision. In the fovea only cones are present. In the region external to the fovea each cone is surrounded by a group of rods, and the number of rods to cones increases as portions of the retina further from the fovea are taken, except at the extreme periphery, where, again, only cones are found. In the outer segment of each rod there is a rose colored substance, the visual purple, which is photochemically sensitive to light. This visual purple is not found in the cones, but only in the rods. For this reason it was not considered to be essential to vision, because it was absent from the cones, and only cones are to be found in the fovea, the region of most distinct vision. Though the visual purple is not present in the cones of the fovea, it is found between them, four special canals aiding the flow from the periphery to the centre of the fovea. When there is no visual purple in the fovea it is blind, as shown by the varying sensitiveness of the fovea and the disappearance of objects in the central area of vision when there is no stimulation of the periphery. The rods and cones project into a thin layer of fluid, which is kept in its place by a membrane. The visual purple is diffused into this liquid and on being decomposed by light stimulates the cones, thereby setting up a nerve impulse, which causes the sensation of vision. The movement of afterimages shows that the stimulus in vision is fluid and situated outside the cones. The rods are not percipient elements but regulate the formation and distribution of the visual purple.

PHYSIOLOGICAL BASIS

The decomposition of the visual purple by light stimulates the ends of the cones, and a visual impulse is set up which is conveyed through the optic nerve fibres to the brain. The character of the impulse differs according to the wave length of the light causing it. Therefore, in the impulse itself we have the physiological basis of the sensation of light, and in the quality of the impulse the physiological basis of the sensation of color. The impulse, being conveyed along the optic nerve to the brain, stimulates the visual centre causing a sensation of light, and then passing on to the color perceiving centre, causes a sensation of color. But though impulses vary in character according to the wave length of the light causing them, the color perceiving centre is not able to discriminate between adjacent impulses, the nerve cells not being sufficiently developed for the purpose.

There are no difficulties in this transmission which do not apply with even greater emphasis to direct stimulation of the cones. Nerve impulses may differ in rate as stated by Keith Lucas. Though the position of the visual centre in the brain has been accurately determined, the position of the color vision centre is still unknown. It may, indeed, be in some portion of the visual tract between the eye and the visual centre. For instance, one portion of the end of the cone when stimulated may possess fibrils which are either connected with, or pass through, a portion of brain giving rise to the sensation of red, whilst stimulation of the other end of the cone stimulates fibrils which, with their neural connections, give rise to the sensation of violet. The intermediate portions give rise to the sensations of green, yellow and blue. It is probable that the nerve impulses bear a simple relation to wave length and there is certainly a remarkable coincidence.

Even with the normal sighted there is room for much further development in the discrimination of color, but when the development is not up to the normal standard or there is a defect in any portion of the apparatus diminishing the power of discrimination, color blindness is the result.

THE EVOLUTION OF THE COLOR SENSE

The wave length of the physical stimulus is the physical basis of the sensation of color. How did the sensation of color first arrive? Let us suppose that the physiological effect of the physical stimulus differed according to the wave length of the physical stimulus. At a certain stage the eye had become sensitive to a fair range of the spectral rays, that is to say, evolution had proceeded to the extent of making the protoplasm sensitive to rays of light considerably above and below those which first caused a sensation of light. There was then an eye which was sensitive to the greater part of the rays which form the visible spectrum. It was, however, an eye which was devoid of the sense of color, no matter from what part of the spectrum the rays were taken. The only difference appreciated was one of intensity. Let us now suppose that a fresh power of discrimination was added to the eye and that it became able to discriminate between different wave lengths of light. What would be the most probable commencement of development of the sense of color? Most probably the differentiation of the physical stimuli which were physically most different. That is to say, the eye would first discriminate between the rays which are physically most different in the visible spectrum, the red and the violet, that is presuming that the eye had become sensitive to this range. We have examples of cases of defective light perception in which there is shortening of the red or violet end of the spectrum.

Let us now work out the evolution of the color sense on the assumption that the rays which are physically most different, namely red and violet, were those which were first differentiated. We know that the various rays differ in their effects on substances, the red rays are more powerful in their heating effects, whilst the violet are more active actinically, as is well known by the readiness with which they act upon a photographic plate.

We should now have an individual who would see the spectrum nearly all a uniform grey of different degrees of luminosity but with a tinge of red at one end and a tinge of violet at the other. There is a great deal of evidence to show that this is how the color sense was first developed. For instance, in the degree of color blindness just preceding total, the spectrum is seen in this way.

It will be noticed in the first evolution of color that the added power of discrimination is something distinct and separate from light perception. It can be destroyed as by mixing the two colors without interfering with the perception of light. Here we have the foundation for the distinction between light and color perception the proper recognition of which is so essential in physiological optics. As the color sense developed it was not necessary that the rays should be so far apart before a difference was seen, so the two colors, red and violet, gradually encroached on the grey band until they met in the centre of the spectrum.

We have now a series of cases each of which only sees two colors, red and violet, with a varying degree of grey band in the centre of the spectrum. We should expect that those who had the smallest white region left in the centre of the spectrum would have the best color perception, because they belong to a later stage of evolution.

Cases of color blindness are found corresponding to all these degrees, from almost total color blindness to those bordering on the trichromic.

In all the dichromics a mixture of the two colors which they perceive, namely red and violet, will form white and so we have the foundation of complementary colors.

The next stage in the evolution of the color sense was when a third color appeared at the third point of physiological difference, that is in the centre of the spectrum in the position of the green.

The color sense now assumed a trichromic form, red, green, and violet, being seen in the spectrum.

As green replaced the grey which existed in the spectrum of the dichromic we should expect that green should be complementary to the other two colors combined, and this we find to be the case.

We have now reached the stage in which three distinct colors were seen in the spectrum, namely red, green, and violet, and the vision had assumed the trichromatic character which must henceforth remain.

When the green was first developed it was a comparatively unimportant color. As evolution proceeded the power of differentiation occurred in the regions between the red and the green, and the green and the violet until a stage was reached in which a fourth color, yellow, was seen at the next point of greatest physiological difference.

The next step in the process of evolution occurred when the retinocerebral apparatus was able to differentiate a fresh color between the green and the violet, namely blue, five definite colors being seen in the spectrum. It will be obvious that in any further evolution the intermediate portions will be still further differentiated and so we arrive at those who can see six and seven colors in the spectrum, respectively.

It is not necessary to consider the further evolution of the color sense because I have not met with a person who could distinguish more than seven definite colors in the spectrum.

CRITICAL CONSIDERATION OF THEORIES OF VISION AND COLOR VISION

One of the most popular theories is the socalled duplicity theory of Von Kries. This supposes that the rods are percipient elements for perception in a dim light, whilst the cones are the percipient elements in daylight. This theory is a very irrational one, for it is difficult to conceive an element stimulated by the decomposition of a photochemical substance which is excited by a weak light and not more strongly by a brighter light. What is the supposed function of the rods during the daytime? Apart from the numerous facts against this theory, it will be found that it is supported almost entirely by misstatements namely, 1, that certain animals have only cones, and others have only rods; 2, that the periphery of the retina is color blind; 3, that the eye is totally color blind in dark adaptation; 4, that the Purkinje phenomenon and the recurrent image are not found with the fovea. With regard to these I offer the following criticisms:

1. Though I have examined numerous collections, I have never been able to find any animal with only rods or only cones, neither have I found anyone who has seen such a retina. The tortoise is the most quoted; it is stated to have only cones. The rods and cones in the retina of the tortoise are as clearly

defined and distinct as in the human retina. 2. The periphery of the retina is not color blind when colors of sufficient intensity are used. The reader can test this for himself with a doctor's red lamp. We will find he can see it as red to the extreme periphery. 3. In dark adaptation the eye is not totally color blind. Those interested in the subject should read the masterly paper by Burch on Color Vision by Very Weak Light (1). Further, there is no scotoma or blind area corresponding to the rod free portion of the macula which is equal to a visual angle of about three degrees. 4. The Purkinje phenomenon and recurrent image are found with the fovea.

It is difficult to comprehend how vision can take place on this theory. How are the central connections in the brain arranged in order to obtain localization, especially with a large scotoma in the most important part of the field of vision? It has been shown that this scotoma only exists in certain circumstances. As a small red light is quite visible on a dark night, and this is seen with the fovea, calculation will show the very small amount of light falling upon the eye, by which it is visible.

How on this theory are the transparent cones stimulated by light? The laws of photochemistry require absorption for photochemical action.

THE TRICHROMATIC THEORY

The trichromatic theory has been very imperfectly understood; it presupposes three elementary and independent sensations, the stimulation of which in various proportions causes all sensations of color. According to this theory, therefore, there are three separate kinds of light sensation, and there is no fact supporting this hypothesis. Normal color vision is trichromatic, and it is trichromatic on my nonelemental theory, but it is trichromatic in the sense of color only and not in the sense of perception of light intensity. The facts of color mixing do not, as is so often stated, support the trichromatic theory because the facts are equally well explained by other theories, including my nonelemental theory. On the trichromatic theory, light of a certain wave length, no matter what may be the source, stimulates in definite proportions one or more of the three fundamental sensations. Therefore, exact matches are supposed to have similar physiological bases.

Now each set of facts requires a different set of fundamentals, which makes the theory quite untenable. Let us compare, for example, the fundamentals of Abney and Burch. Abney gives the red sensation as affected by light of all wave lengths, Burch gives the red sensation as affected by light from λ 760 $\mu\mu$ to λ555 $\mu\mu$ with other points of difference. Abney gives λ548 $\mu\mu$ as stimulating the fundamentals, in sensation luminosities in the following proportions: red sensation 49.7, green sensation 35.6, and blue sensation 0.035. Dr. Troland writing on the same subject, using the word minuthesis instead of fatigue, gives his results as follows:

"The general conclusion to be drawn from the work is, therefore, that minuthesis due to one color does not alter the luminosity of another color to a degree differing appreciably from that in which it is altered itself. In other words, the change in sensitivity to brightness occasioned by stimulation of the retina is independent of the wave length constitutions of the minuthetic and of the reacting lights. This seems to imply that the luminosity function is not essentially linked with the color or chromatic function and stands in contradiction to the views of Abney, Ives, and others who treat luminosity as the sum of the primary color values of any stimulus. The present results appear also to conflict with experimental data along similar lines published by Abney and by Burch, so that further study of the problem would seem to be required on a larger number of subjects." These results are in agreement with those of A. W. Porter and myself (2).

If the eye be fatigued with pure yellow spectral light the spectrum will appear to have lost its yellow, and though yellowish red or yellowish green will appear less yellow the terminal red of the spectrum will not be affected. If the terminal portion of the red end of the spectrum be isolated in my spectrometer it will appear as a faint red upon a black background. If the eye be fatigued with red light even by looking through a red glass held against a light for one second, the red will not be visible for some considerable time, but the eye may be fatigued for twenty minutes with yellow light without interfering with the visibility of the red light. It should be noted that Abney gives the percentage composition of the sensations stimulated by light of τ 585 $\mu\mu$ as 75 red sensation, 25 green sensation, therefore on the trichromatic theory fatigue by yellow light fatigues the red sensation.

Besides being loaded with subsidiary hypotheses inconsistent with each other, the differences between two presentations of the theory are as distinct as two independent hypotheses. Abney gives the violet as a compound sensation having the percentage composition of 72 red sensation and 28 blue sensation. Burch gives very strong evidence showing that violet is a simple sensation. If the positive after image of a complete spectrum be obtained it will be noticed that it disappears from the red to the violet end. If yellow consisted of a mixture of red and green its positive after image should change to green before disappearing; this is not the case and can be tested in the following way. In an absolutely dark room, if pure spectral yellow light be thrown on a white screen and a flicker apparatus rotated slowly in front of it, the yellow will not change its hue.

Whilst the nonelemental theory given is in complete agreement with all the known facts of color vision, there is no fact in support of an elemental theory. It is probable that spectral light sets up impulses corresponding to light of adjoining wave lengths and when the stimulation is very violent as in the experiments of Burch who used a convex lens with direct sunlight a considerable range may be affected.

Space will not permit my giving numerous facts showing that yellow is a simple and not a compound sensation. Color blindness cannot be classified on an elemental theory. Abney has endeavored to do this, but check experiments show that his conclusions are untenable.

Fracture of the Hip in Adults*

JOHN T. O'FERRALL, M.D.
New Orleans, La.

Fracture of the neck of the femur has been chosen as the subject for discussion because it is of great importance. It should be brought frequently before gatherings of general medical men, to keep it ever fresh in their minds. Indifferent treatment of fractured hips prevails in all communities. It is frequently looked upon as one of the natural complications of middle life and old age, the treatment of which is useless. This erroneous conception of such an injury is, in my opinion, the result of nonprogressiveness and requires repeated publication of the proved facts in order to correct it. The forward march of surgery has brought forth much of importance in the diagnosis and treatment of this condition. It is my purpose to call attention as concisely as possible to the most important and practical points of both. Such fractures represent a serious problem and require scientific treatment. This does not, however, justify the neglect of such cases so often seen, using as an excuse lack of facilities, for the proper treatment can be carried out in the smallest community. Few serious disabilities are so amenable to treatment and the end result so satisfactory, except in occasional instances. A total disability can be largely relieved and an otherwise helpless invalid restored to usefulness and the joy of living, free from physical dependence.

ANATOMY OF HIP

The anatomy of the hip is intensely interesting and represents a subject for prolonged study in itself. We are particularly concerned at this time with a review of the structure of the neck and head of the femur and their blood supply; together with the important ligamentous attachments. To quote from *Gray's Anatomy:* "This arrangement of the cancelli in the ends of the femur is remarkable. In the upper end they are arranged in two sets. One set, starting from the top of the head, the upper surface of the neck, and the great trochanter, converges to the inner circumference of the shaft; these are placed in the direction of greatest pressure, and serve to support the vertical weight of the body. The second set are planes of lamellæ intersecting the former nearly at right angles, and are situated in the line of the greatest tension—that is to say, along the lines in which the muscles and ligaments exert their traction. In the head of the bone these planes are arranged in a curved form, in order to strengthen the bone when exposed to pressure in all directions." In this connection, a recent article in the *Journal of Bone and Joint Surgery* by Anatole Kolodny reports an exhaustive study of the upper femoral end. He says: "A good, clear röntgenogram of a femur sectioned in different planes shows other interesting points of structure. The neck of the femur seems to consist of bone lamellæ which arise from the shaft and extend from it in a rather peculiar way. The bone lamellæ which arise from the external side of the femur shaft (external condyle) arch towards and run farther in the neck, continue there and end in the femoral head perpendicular to its surface. These bundles of trabeculæ prevent the laceration of the neck; they are the tension lamellæ. From the internal condyle other bundles of bone trabeculæ arise which run to and into the neck, cross the tension lamellæ at a right angle and end in the femoral head perpendicular to its surface. These are the pressure lamellæ. They counteract the compression of the neck. In arching towards the femoral head and neck both groups of bone lamellæ wind spirally.

"The crossing of the tension and pressure lamellæ takes place mainly in the femoral head. The head is composed of a scanty substantia compacta and of numerous spongiosa trabeculæ which are arranged like the spokes of a wheel. These trabeculæ are interwoven with those which come from the neck, interlacing like the groins of a gothic arch. Besides the tension and pressure lamellæ described above, there are bundles of bone lamellæ which run from the lamina femoralis interna to the great trochanter. These lamellæ cross the tension lamellæ at right angles. As is seen, all these three systems of bone lamellæ describe, by their main masses, a triangular space which is poor in bone trabeculæ. This is Ward's triangle (trigonum internum femoris), mentioned by Ward in 1838. Our study leads us to believe that this triangle is the point where atrophy and rarefaction of the upper femur begin in general skeletal atrophy and in old age. While in young, strong, muscular and bony persons the triangle is filled with spongiosa bone, in elderly persons this space is lacking any bone trabeculæ, and because of this it diminishes the margins of safety of the femoral neck, and is therefore a locus minoris resistentiæ of the femoral neck. Fractures are produced through this area when the isolated femur is subjected to vertical compression."

The most important ligaments attached to the upper femur are the a, iliofemoral; b, ischiofemoral and c, the capsular ligaments. The shortening found in cases of fracture of the neck is produced by the upward pull of the muscles attached to the greater trochanter and possible shortening of the iliofemoral or Y ligament. This ligament is attached above to the anterior inferior spine of the ilium and passes over the front of the joint and neck of the femur in two bands, one of which is attached to the anterior surface of the intertrochanteric line at the lesser trochanter and the other into the same line near the junction of the neck and the greater trochanter. The ischiofemoral ligament is a short band extending from the ischium, just below the acetabulum, to the posterior surface of the neck of the femur, blending with the circular fibres of the capsule. Kolodny's dissections indicate that this ligament checks internal rotation and when the neck of the femur is fractured this ligament is made more tense by hemorrhage and engorgement, thus producing external rotation of the leg or eversion of the foot.

*Read before the Rapides Parish Medical Society, Alexandria, La., August 3, 1925.

The capsular ligament is attached above to the acetabulum and the cotyloid ligament. It envelops the head and neck of the femur and is attached below to the intertrochanteric line in front; above to the base of the neck; behind to the neck about one half inch above the posterior intertrochanteric line. From this insertion the fibres are reflected upward over the neck of the femur, forming a tubular sheath. It is this reflection which may be the interposing soft parts in some cases of ununited fracture of the femoral neck.

BLOOD SUPPLY OF HIP

In discussing fractures of the femoral neck, consideration of the blood supply is of great moment. It is still a question as to the exact vascular nutrition of the hip. *Gray's Anatomy* states, in describing the neck of the femur, that the anterior surface is perforated by numerous vascular foramina, the posterior surface is smooth and the superior border is also perforated by large foramina. No description of the inferior surface is given. It is apparent from this statement that vascular nutrition of the femoral neck is derived, to a considerable degree, from the periosteum. Kolodny states that the head and neck of the femur receive blood supply also through the ligamentum teres, the epiphyseal bloodvessels and the diaphyseal vessels, in the child and the newborn. In middle and advanced age the ligamentum teres is very much atrophied and often absent; its blood supply is therefore of little consequence.

Upon fracturing the femoral neck the diaphyseal bloodvessels are broken along with the bone tissue, and another source of vascular nutrition is taken away from the femoral head and neck. If displacement of the fragments occurs, the periosteal branches are torn and the head of the femur is then entirely dependent upon the few epiphyseal vessels to give it nutrition. Trauma often disturbs these latter vessels and the head of the femur is left without sufficient blood supply. It is no wonder then that marked atrophy of the head and complete absorption of the neck so often occurs in fractures of the type under discussion, especially when inadequate treatment is given. Kolodny correctly says, "prognosis of a fracture of the neck depends entirely upon the displacement and angulation of the fragments." It is frequently advised that impaction of fractured femoral necks should be broken up and the fragments subsequently reduced. I am convinced that impaction in such instances should not be disturbed. The end results experienced justify this assertion. Impaction of fractures, in general, should not be broken up, unless a joint is involved or unusual deformity exists.

CAUSES OF HIP FRACTURES

These fractures occur principally in patients of middle and advanced age. Twenty-seven per cent. of all fractures of the femur are of the neck. Recent experience has shown that they occur more frequently from the age of forty upward than was formerly thought. Among the aged, females are affected more often than males. Except in industrial cases, the injuries producing these fractures of the neck of the femur are slight. Such mild trauma as stepping unconsciously from an elevation of a few inches often produces the disability. Unquestionably, direct trauma (or indirect trauma transmitted directly to the neck of the femur) generally is the exciting cause of the fracture; however, in many instances the fracture occurs from simple superimposed weight before a trauma or fall occurs. In other words, vertical compression has occurred. According to Kolodny, the majority of fractures occur as the result of a fall on the hip (trochanter), which fracture is then produced by trochanter lateral compression. The history in such fractures often reveals such simple accidents as tripping on a rug, stepping from a car or carriage quickly or slipping on a wet pavement.

CLASSIFICATION OF FRACTURES

The types of fractures of the femoral neck are divided into two classes, first, intracapsular and second, extracapsular. This classification is not accurate because of the oblique attachment of the capsule on the femoral neck. Thus many fractures are partially extracapsular and partially intracapsular. In most instances they are entirely intracapsular. A more accurate classification is, first, fractures at the base of the neck, and second, fractures of the neck near the head. Various authors maintain that the former are by far the most common, especially in the aged.

The question of impaction in these fractures has been previously alluded to. I would like to emphasize, however, that impaction is a condition of value in healing in these conditions rather than a menace.

DIAGNOSIS

The diagnosis of such hip fractures is generally not difficult. The history of a fall or a sudden twist of the leg, especially in a person of middle or advanced years, is generally related. Inability to arise after the fall, associated with soreness in the region of the trochanter is fairly typical. It may happen, however, that impaction has occurred and the patient is able to walk for some distance, although with pain. One patient, in my experience, walked up a flight of stairs to her bedroom, then to the bath and back again, without great difficulty. The pain is generally referred to the region of the trochanter but may be intense at the knee. This latter area may be the only painful one and should always be kept in mind by the examiner. The patient should be examined properly draped but free of all clothing. Swelling and redness are absent, unless the trauma has been direct and severe. External rotation of the leg, frequently spoken of as eversion, always exists. This position is produced largely by the ischiofemoral ligament and the rotators of the thigh. Careful measurement of the legs reveals shortening of the affected member, varying with impaction and complete fracture, greater, of course, in the latter. Any attempts at manipulation of the hip greatly increase the pain in the hip or that referred to the knee. The trochanter is above Nelaton's line. Crepitus may be made out in complete fracture but is absent in cases of impaction. Prolonged search for crepitus or abnormal mobility should not be attempted. In cases of complete fracture the patient cannot lift the affected heel from the bed. By keeping in mind the above signs and symptoms along with gentle palpation, the diagnosis is generally made without difficulty.

X ray examination is, of course, not only desirable, but necessary. These radiographs should, if possible, be made stereoscopic and of both hips. In any event, an exposure of both hips should be made. This is particularly important if the plates or films are to be read by one who has had a limited experience, as any abnormality is more readily recognized by means of comparison.

METHODS OF TREATMENT

In order to facilitate discussion of the treatment of these fractures of the femoral neck, it seems wise to divide them into two types, namely, a, surgically nonoperative, and b, operative treatment. The former method is the one we are most frequently called upon to carry out and the results therefrom are most satisfactory. The latter method we find necessary to use in the cases of nonunion, a limited number of which occur irrespective of the type of treatment used from the time of the occurrence of the fracture; and many result from indifferent and improper treatment.

NONOPERATIVE TREATMENT

The surgically nonoperative type of treatment is so designated to indicate that no open operation is done. As is the case in the treatment of all fractures, our first efforts are directed toward complete reduction and maintenance of the bone fragments in apposition. This is of even more importance in fractures of the femoral neck because of the poor nutrition of the bones involved. The abduction method of reduction and fixation for these cases as described by Royal Whitman meets these requirements in an almost ideal way and takes precedence over any other method of treatment. This is not only a personal opinion, but I am supported in it by such men as Scudder, Brackett, Osgood, the Mayo Clinic, and numerous other surgical men throughout the world. To quote Whitman's own words in describing this method is interesting.

The abduction method has three great advantages over any other method—comprehensive mechanical effectiveness, single control, and general availability. In fractures of the neck of the femur, the head being fixed in the acetabulum, the displacement is always of the outer, or limb, fragment. If the separation is complete the displacement is usually upward, backward, and outward, and to oppose the fragments the limb must be lifted forward, rotated inward, and drawn downward to its normal length. But, since the neck of the femur projects from the shaft at an angle, the apposition is in a lateral relation and is unstable because there is no point of resistance. If now the limb be abducted to the normal limit, the extremity of the neck is brought down to a horizontal plane. As the capsule surrounds each fragment, its tension, consequent on abduction, aligns them, and since the head is fixed by the acetabulum, it forces an end to end and resistant contact. Furthermore, at the limit of abduction the upper border of the shaft fragment and the trochanter are opposed to the rim of the acetabulum and the side of the pelvis. Thus, security is assured by the tense capsule, by direct and indirect bony contact, and by the muscular impotence incidental to the attitude of complete abduction.

When this adjustment has been accomplished, a long plaster spica is applied, fixing the limb in full extension, full abduction, and slight inward rotation. Although the spica is a direct support, its chief function is to hold the limb in the selected attitude that makes the internal or anatomical splinting effective, as may be demonstrated by x ray examination through the plaster at intervals of weeks or months.

The abduction method is adequate because it utilizes the construction of the joint and its mechanical environment to reduce deformity and to fix fragments in apposition.

The plaster spica is applied with the patient under a general anesthetic and preferably on a fracture table, but any sacral rest will answer. The legs are extended by two assistants until the shortening has been overcome, as demonstrated by actual measurements. The affected leg, which is generally in outward rotation, is then rotated internally until the patella points slightly inward. With traction still being exerted, both legs are abducted to the normal limit. The plaster is then applied, including the foot, and the portion including the body should be much higher opposite the affected leg to assist in preventing adduction. The knee is slightly flexed in the plaster to relieve strain and discomfort.

There is some argument against the use of a plaster spica for the treatment of the middleaged and those older, on the grounds that it is uncomfortable. This is a great error and undoubtedly arises from ignorance and inexperience. It is a great advantage over methods requiring extension, as the patient can be turned from side to side and even on the abdomen, this, of course, assisting in the prevention of hypostatic pneumonia, bedsores, etc. The head of the bed is usually raised one to two feet, which is more comfortable and gives the patient an easy view of her surroundings. It also promotes the circulation to the affected leg and hip, thus assisting repair. The patient often is able to get around on crutches in the spica and in the wheel chair or on a carriage. The spica remains on for a period of from eight to twelve weeks. The removal of the splint is followed by rest in bed and massage. Weight bearing should not be permitted under six months and often longer, depending upon the rapidity of repair. A weight bearing caliper splint is advisable to transfer the weight to the pelvis rather than to be borne by the affected femoral neck.

By far the greater number of favorable results are obtained by the abduction or Whitman method. There are, however, other methods which give favorable results in some instances but with which the same degree of complete reduction and accurate apposition cannot be assured. Any method, the guiding principle of which is extension and counter-extension, is of very great disadvantage. It is exceedingly trying on the patient to remain continuously on her back or even in the semirecumbent position. Such posture furthermore increases the danger of hypostatic pneumonia, and almost certainly bedsores will result. All of the remaining methods to be mentioned have this principle of extension and are therefore considered unsatisfactory.

Scudder reports the results existing in sixteen cases of fracture of the hip many years after the accident. These sixteen cases were treated by trac

tion and immobilization for periods varying from a few weeks to a few months. The patients then went about with crutches. No other treatment was used. Nearly all the cases were unimpacted either primarily or secondarily. At the time of the accident seven patients were between forty-two and forty-seven years old, the remainder, except in two cases, were over fifty; three were over sixty years old. These patients reported for examination from two and a half to twenty-four and a half years after the accident. Thirteen of the sixteen patients have impairment of the function of the leg; a weakness of the limb, requiring a crutch in many instances; atrophy of the affected member; limitation of motion of the hip; pain in the hip often requiring a cane. The conclusion is evident that the old time method of treatment of hip fractures by extension is not productive of satisfactory results.

The Maxwell-Ruth method is often suggested and it employs traction in two directions, i. e., longitudinal and lateral extension. It is probably the most important of the traction methods but has the disadvantages described above. The same can be said of the Hodgins splint, the overhead suspension traction methods and numerous other adaptations of these last mentioned. I have even heard it recommended that patients with these fractures be treated with rest in bed and the affected extremity supported only with sand bags. Occasionally a fracture of the femoral neck firmly impacted might recover with such treatment but it could not be considered a method supported by good surgical principles and sound judgment.

OPERATIVE TREATMENT

The operative type of treatment applies to those cases of fracture of the femoral neck in which bony union has not taken place or in which a painful fibrous union is the result. These cases usually come to the orthopedic consultant many months or years after the initial injury. The greater part of the neck is absorbed and the shallow head is left in the acetabulum. The trochanter and upper end of the shaft have no fixed position and the leg is almost entirely useless.

The causes of nonunion are not numerous and are easily explained. A certain number of fractures of the neck will result in nonunion irrespective of the type of treatment given from the time of the accident. This state of affairs is undoubtedly due to interruption of a large part of the circulation to the part involved, namely, the neck and head of the femur. As I have previously pointed out, a fracture through the neck deprives the head and the remainder of the neck of the diaphyseal circulation, and if the fragments are displaced the periosteal vessels are also ruptured, leaving only the epiphyseal circulation, which in the middleaged and older subjects is scanty. The formation of callus is therefore practically impossible even though the fragments are in fair apposition.

Inadequate treatment of course accounts for many cases of nonunion. The attending physicians often forget the necessity for complete reduction and careful maintenance of the fragments in apposition. Indifferent treatment is not a deliberate act but often occurs because the patient is old and the physician fails to realize that the treatment above described is far more comfortable than the long period of suffering and invalidism accompanying nonunion.

Interposition of the capsule of the hip or its reflexion at times occurs. This is especially true if the hip is not completely abducted and full advantage taken of the tubelike shape of the capsule acting as a coaptation splint.

Early weight bearing may be the cause of nonunion, whereas, if it had been avoided a functional result would have existed. It must be remembered that the formation of callus is directly dependent upon circulation. In this area under discussion, where circulation is so poor, the throwing out of new bone of necessity will be very slow, requiring a much longer time for complete healing. Long fixation in good apposition is necessary, checked up frequently by radiographs before weight bearing should be considered. Even then a properly fitted caliper splint should be worn to protect the injured hip.

The existence of constitutional diseases, such as syphilis and tuberculosis, exert their influence on the formation of new bone and thus may be the cause of nonunion.

There have been numerous methods of operation suggested for the repair of ununited fractures of the femoral neck. The more practical methods will be described in detail and some of the remainder mentioned.

As I said in a previous paragraph, these patients usually come for consultation and treatment many months or even years after the injury. The patient is unable to take her weight on the affected leg and pain is bitterly complained of in the hip and the sciatic distribution. Crutches are necessary. Pain often prevents sleep. Physical examination reveals the disability at once. There is marked external rotation, inability to raise the heel from the bed, marked shortening and unusual mobility of the hip joint. The x ray examination shows a complete absorption of the neck of the femur and only the devitalized head in the acetabulum. A study of the radiographs will show the absolute futility of using bone grafts, bone or metal screws, or large metal nails in an effort to bring the fragments into apposition. Even if it were possible to do so, union could never take place between the devitalized and fibrosed surfaces of the fragments.

TECHNIC OF BRACKETT'S OPERATION

The method of choice, without doubt, is that described by Dr. E. G. Brackett, of Boston, and which, concisely stated, is the transference of the head of the femur to the trochanter. An incision is made from the anterior superior spine of the ilium to the middle of the trochanter, turning downward, parallel to the shaft of the femur, for six inches or more. A counter curved incision is then made, at the angle made by this incision over the trochanter, extending backwards and upwards three or four inches. The tensor fascia femoris and gluteus medius are separated, the muscle attachments on the outside of the trochanter are removed subperiosteally, or with a thin bone attachment, and the top of the trochanter removed so as to save the attachment of the gluteus minimus and pyriformis. These muscles are then all turned backwards and upwards, and the upper and anterior portion of the capsule exposed, to the edge

of the acetabulum. The capsule is opened longitudinally to its fibres, on the upper portion of its anterior surface, saving the attachment of the Y ligament, if possible, but which cannot always be done. The trochanter is cut off just below the level of the upper edge of the head, the inner portion of the shaft rounded to correspond to the curve of a one and a half to two inch radius. The outer end of the shaft is cut off obliquely. The free surface of the head is thoroughly freshened and a curved depression fashioned in it to correspond to the curved inner end of the shaft being brought directly into the concaved head, and in this position is firmly held against it. In this way the femoral head with its freshened surface is placed directly on the freshened cancellar surface of the trochanter.

It is to be noted that the head is placed on the inner side of the femoral shaft and not on the end of the trochanter. Upon reassuring oneself that the head and shaft are in the relation desired the capsule is closed, the leg being held in this position until the operation is finished and the plaster spica applied. The small pieces of bone with the attachments of the gluteus medius and minimus, and pyriformis, are secured to the outer side of the shaft or to the periosteum. The wound is then closed in layers and the plaster spica applied. This plaster splint should extend well up to the chest wall on the side opposite the affected leg, to prevent abduction, and it should also include the unaffected thigh to the knee and the affected leg and foot. The position of the foot should be very slight internal rotation. Fixation should be continued for two to three months, followed by change of plaster and x ray examination. Two to three additional months of fixation should then be required before weight bearing is allowed.

A very interesting and important fact to be observed in this operation is that there is practically no shortening of the affected leg. The new neck and head permits an unusually large range of motion, especially in abduction and flexion. Among the lantern slides will be seen the results obtained in a case I have recently operated upon. The patient is walking, using crutches, as her period of weight bearing has just begun. It is important, in considering a patient for this operation, to be sure that no arthritis involving the femoral head exists. If such a condition was overlooked a very painful and disappointing end result would ensue. It would seem in cases in which an arthritis of the head exists that the Whitman reconstruction operation is indicated and would give a painless and stable result.

WHITMAN OPERATION

The Whitman reconstruction operation may be performed through the incision and approach described for the Brackett operation. There are of course numerous methods of approach to the hip joint to meet all existing conditions. "This operation," says Whitman, "is primarily designed for the treatment of ununited fracture of the neck of the femur in which direct union of the fragments by bone grafting or other means is doubtful or impracticable." It seems particularly useful in cases in which an arthritis of the head exists in addition to the fracture. (As long as the head of the femur is in good condition the Brackett operation is the method of choice.)

OBJECT OF SURGICAL TREATMENT

Since these patients suffer a great deal of pain in addition to the functional disability, the object of surgical treatment is to relieve the former and restore the latter. This operation is known as a reconstructive one because it restores stability in weight bearing with a fair range of controlled motion. The head of the bone is removed from the acetabulum. The trochanter is then cut off at the base on a line with the neck. It is turned up with its muscular attachments. The projection of the shaft, shaped somewhat like a new femoral neck, is trimmed up as required and inserted into the acetabulum. In order to accomplish this the leg must be abducted to about 25 degrees. A new bed for the detached trochanter is then made by elevating the periosteum and removing a small section of the cortex at the point on the shaft to which the muscles attached to the trochanter will allow it to come. It is sutured down in this bed as firmly as possible to insure bony union. The leg is then fixed in a plaster spica in abduction for several weeks until the trochanter has firmly united. Passive and gradually increasing active motion is then begun. The limb is used in slight abduction and the range of motion is sufficient for ordinary function. The operation is fairly quickly done and may not produce excessive shock even in an individual already weakened by long confinement.

OTHER METHODS OF TREATMENT

The medical literature is full of articles referring to and advocating the use of bone grafts, iron nails and screws, bone screws and ivory pegs for the repair of these ununited fractures of the femoral neck. Even a casual glance at the x ray negative of the average ununited fracture of the neck will convince you of the mechanical impossibility of bringing the fractured surfaces in contact by any of these methods. The greater part of the femoral neck is absorbed, thus preventing apposition and even if such could be accomplished the surfaces of the fragments are covered with a very dense, resistant fibrous tissue, preventing the throwing out of new bone tissue.

Ununited fractures of any bone and especially of the femoral neck cannot be considered as such until proper apposition has been accomplished and ample opportunity given to permit union. Certainly we are not justified in using any of these methods of open operation and the insertion of various foreign substances early in the treatment of the fracture and before opportunity has been given for union in the usual, ordinary way. Local literature has contained several articles recently advocating the use of metal screws as soon as the fracture occurs. I am sure you all agree that this is surgically unsound because it violates all the recognized laws for the treatment of fresh fractures; it subjects poor surgical risks already shocked to greater shock and opens up avenues to infection which need not exist. We all know that bone tissue and also soft tissues resent metallic foreign bodies and the percentage of infections from their use is large, even if perfect technic, as advocated by Lane, is used. I dare say few of us would submit to such treatment with the facts outlined above before us. This method is not a new one but was used many years ago, and justly discarded.

Observations on the Minimization of Deformity and Disability Following Fractures*

MARK COHN, M.D.
New York

I am sure that most of us see some end results following fractures, that are not entirely satisfactory either to ourselves or to the patient. In some of the cases the resulting deformity and disability are inevitable because of the nature of the injury. In others, however, we cannot escape the feeling that the end result could have been better. It cannot, therefore, but be of the greatest interest to consider some of the ways in which deformity and disability following fractures can be minimized.

The goal that we must keep foremost in our minds in the treatment of fractures is to obtain restitution of function with as little deformity as possible. In order to obtain this, proper reduction of the fragments is necessary. As reduction is in most instances a very painful procedure, it is highly desirable that the patient be given a general anesthetic. This not only makes the procedure painless, but also causes a relaxation of the muscles, preventing them from pulling the fragments in an abnormal direction. Proper alignment and apposition of the fragments is thus more easily obtained.

While it may hardly seem necessary to mention the importance of x ray pictures both before and after reduction, many instances are still seen where the practitioner does not take advantage of this very important aid to diagnosis and treatment.

The doctor must safeguard the patient's best interests and also protect himself. If only from purely selfish motives he should not place himself in a position where he will be open to criticism and liable to be sued for malpractice.

Apropos of this, Mr. R. C. Elmslie, orthopedic surgeon to St. Bartholomew's Hospital, London, quoted in a letter to the *Journal of the American Medical Association* (December 31, 1921, p. 2132) states that "Every case of fracture should be treated as a possible medicolegal one. If a röntgenogram is not taken the reason should be stated in writing. Physicians should not commit themselves to statements as to the nature of the injury without röntgen ray evidence."

Sir Robert Jones in his *Notes on Military Orthopedics* states that malunion of a fracture can always be prevented and should raise a strong presumption of inefficient treatment. X ray pictures are essential in the treatment of fractures to prevent deformity.

If the case warrants it we should not delay calling in additional assistance. If we assume entire responsibility of the case we run the risk, if the result is displeasing to the patient or his kin, of a suit for malpractice.

Of course. a proper knowledge of the anatomy and mechanics of the injured part is essential. If there is overriding of the fragments in fractures of the long bones sufficient traction must be applied to overcome this deformity.

In the reduction of a Pott's fracture the relation of the foot to the leg must be restored in such a way that after the fracture has healed the weight bearing line passes through the ankle and foot as near to the normal as possible and that the motions of the ankle joint and tarsus be conserved.

After reduction has been accomplished it is necessary to place the part at rest in a position which will best maintain proper alignment and apposition of the fragments. It is an inherent characteristic of living tissue when it is injured to undergo a healing process. In his treatment the physician can only assist Nature's method and the best way to do it is to place the part at rest. This is done by means of sand bags, splints, plaster cast, brace, etc., according to the age of the patient, location of the fracture and other circumstances.

One of the important points in immobilizing is to make sure that the circulation of the part is not interfered with. It is best to postpone the application of the final immobilizing dressing until the swelling of the soft parts has reached its maximum. If a plaster cast is used it can be split longitudinally down to the cotton to allow for any possible additional swelling. The dressings should fit firmly but not too tightly. Bony prominences subjected to pressure should be well padded. When applying plaster of Paris bandages they should be rolled on with just the proper tension.

After the application of immobilizing dressings to the extremities the color of the fingers and toes should always be observed for circulatory disturbances. For this reason the tips of the fingers or toes should remain uncovered when applying dressings which include the hand or the foot. Nowadays we do not see many cases of socalled Volkmann's ischemic paralysis which result from interference of circulation of the part while it is immobilized.

Now let us consider the important problem of conserving and restoring function. It may be stated as a general principle that when a part is immobilized, it should be held in that position which will be most favorable to the return of normal function when the injury is healed.

While the fracture is healing under the immobilizing dressings the physician can materially assist in the early restoration of function. Passive motion of the neighboring joints can generally be cautiously begun during the first week.

We have seen a considerable number of cases of fractured forearms, especially in elderly persons, who in the course of, or after treatment, complained of pain and stiffness of the shoulder and arm of the affected side. Examination in these cases showed that voluntary motion of the shoulder joint was considerably restricted and painful as were also efforts at passive motion. The muscles about the shoulder joint showed varying degrees of atrophy. On questioning, the majority of the patients denied the presence of

*Read at the meeting of the North Bronx Medical Society, New York, January 14, 1926.

shoulder symptoms previous to the injury. The symptoms are generally noted at the time when the arm is released from the sling and the cast or splint removed. The cause of this condition is the lack of exercise of the shoulder joint in the course of the treatment. The patient feels more comfortable and secure with his arm in a sling and sometimes even wears the sling in bed. Of course, in the early days of the fracture, this limitation of motion at the shoulder is instinctive because of the pain; but after the first week the patient sees no necessity to move the shoulder. The physician probably does not pay much attention to the shoulder either, his efforts being entirely centred on the fracture itself, and the patient may be allowed to wear the sling until the fracture has completely healed.

The lesson to be learned from this is obvious. In our fractured forearm cases we should do away with the sling as early as possible. Passive motion of the shoulder joint should be begun early and continued daily during the course of the treatment if necessary. The patient should be encouraged to move the shoulder to the normal range of motion in all directions. At first these exercises are best done in the recumbent position by the physician, nurse or a member of the family who has been properly instructed. Care must be taken to make no motion which will disturb the fracture.

Similar conditions are sometimes seen in the joints of the hand, wrist or elbow, in fractures of the arm or forearm. They are generally preventable by early mobilization.

Stimson (*Fractures and Dislocations,* eighth edition, 1917) advises as follows: "In the treatment of all fractures of the arm and forearm the fingers and thumb should be left free and the patient should be enjoined constantly to move them. If the dressing must include the hand it should be so arranged that the wrist will be in slight dorsal flexion, the fingers flexed but free to be extended and the thumb abducted, because these attitudes tend to retard and diminish the ill effects of confinement and lack of use. If the fingers must be confined they should be in flexion."

One of the important adjuncts to the early restoration of function is massage. This should be begun early. It should not be limited to the parts more or less distant from the fracture but can also be applied to the region of the fracture itself.

If the limb is immobilized by a plaster of Paris cast, the cast can be cut into anterior and posterior halves by means of sections along the inner and outer aspects down to the cotton covering the limb.

The anterior half can be lifted off during the treatment, or the cast can be completely cut through on one side only and the front lifted up as if on a hinge. The posterior portion of the cast supports the limb and maintains the proper position.

The massage should be given over the cotton and limited only to gentle stroking movements at first and for a short time. Gradually the movements can be made stronger and the time of the massage lengthened. Naturally there is considerable sensitiveness in the beginning, but this is gradually overcome. It is best to delay the massage for a time if there is much tenderness.

Active motion of the joints more distant from the fracture should be encouraged fairly early and if the patient is slow to cooperate passive motion should not be delayed.

Passive motion of the joints nearest the fracture should be done very cautiously by the physician as early as it is safe to do so; that is, as soon as the fractured member can be handled without fear of displacing the fragments. Care should be taken that the limb is properly supported during the treatment. Only one or two movements need be gone through in the beginning, about every second day, and they can gradually be increased in number at each sitting, but of course well within the point of fatigue. Active motion at these joints should also be encouraged as early as possible.

When the fracture is in the neighborhood of a joint, great care must be taken that motion is not started too soon, as there is more danger of disturbing the position of the fragments in this location.

If the joint has been contused or sprained at the same time as the fracture has occurred, the condition should be treated by rest; and active and passive motions should be delayed until the inflammatory reaction has subsided.

In those cases of injuries to joints where the best possible result that can be expected is bony ankylosis, the injured member should be placed in the position which will be the most useful one after healing has occurred.

Many cases of deformity following fractures of the lower extremity. when all possible care has been taken to obtain and maintain proper reduction and alignment of the fragments are caused by permitting weight bearing at too early a period or without proper support. The greatest care should be taken to delay weight bearing until union has taken place to such an extent that the increased strain which takes place at the site of the fracture during weight bearing will cause no movement of the fragments or any change in their alignment.

Preliminary to weight bearing graduated active movements and resisted movements of the injured extremity should be done under careful supervision. During these movements the physician can determine the stability at the site of the fracture. If it is seen that the union is not firm enough to permit weight bearing these exercises can be cautiously continued with proper support of the limb, in order to stimulate the healing process. These exercises are especially indicated when the healing process is delayed. If the healing process is taking a normal course these exercises should not be begun too early but just as a preliminary test and preparation for weight bearing.

Proper support of the injured part should be continued until there is no doubt whatever concerning the stability of the union. There should always be an intermediate period between that of immobilization without weight bearing and weight bearing free from any external support. During this period weight bearing with support is permitted and the patient is observed at frequent intervals to see that there are no signs of undue strain at the site of the fracture or elsewhere. If there are any untoward signs, weight bearing is not permitted until either the healing process has progressed or the support has been corrected so that weight bearing is made safe.

During this period the support given by the im-

mobilizing dressing is generally sufficient. The patient is permitted to stand and walk with the cast on, at first with the aid of crutches. If everything progresses well the time of weight bearing is gradually increased and the amount of external support gradually lessened until weight bearing without support is safe.

In those cases where the external support cannot be dispensed with, such as in obese persons, elderly patients, delayed or nonunion, a cast or a brace is worn for a variable period.

CONCLUSION

The preceding statements made concerning fractures of the lower extremity apply similarly to the upper. Early massage of the injured limb, early active and passive motions of the joints more distant from the fracture, later active and passive motions of joints nearest the fracture, and then as the healing process progresses, or to stimulate it, graduated active and resisted movements of the limb preparatory to functioning without any external support.

Value of Iodine in the Treatment of Scarlet Fever

Results of a Comparative Study of Two Hundred Cases Treated in the Philadelphia Hospital for Contagious Diseases

HARRY J. NOVACK, M.D.
Philadelphia

It seems rather unusual to advocate iodine—an element with irritant properties—as a new remedy in scarlet fever—a disease whose toxin possesses more or less of a destructive action upon the kidneys, skin and other tissues. With the old teachings still ingrained in our minds, it appears like adding insult to injury to favor the use of iodine or any modification of that element as a therapeutic measure in scarlet fever.

However, from clinical study and experience in private practice as well as corroborative evidence in the following hospital report, iodine, or the particular modification that was used, has proved itself of unusual value in the treatment of scarlet fever.

In the Medical Journal and Record of January 17, 1923, I reported the results of six years of observation and study with a modification of iodine called colodine—a ten per cent. colloidal form of iodine. Among several rather unusual indications scarlet fever was included.

It was long noticed that in the acute tonsillar infections, especially where the streptococcic strains of bacteria were predominant, that the drug had a powerful action in combating that infection. When administered early, its action often was abortive in character, while when given later, the reaction limiting the infection frequently caused increased swelling of the tonsils, peritonsillar tissues, and in some cases, tenderness and swelling of the muscles and glands of the neck.

On several occasions contacts with such reacting tonsillar cases subsequently developed definite scarlet fever and it appeared to the author that some of the sore throats treated might be scarlatinal in nature. Further clinical trial in definitely diagnosed cases of scarlet fever proved the drug to be of more than usual value.

When the drug was given at the earliest possible moment of onset—with the appearance of vomiting, redness of the throat, rash and elevation of the temperature and pulse—the result was semiabortive within ten to fourteen hours following intensive medication. All symptoms rapidly subsided, the rash became blanched so that the skin appeared faintly bluish or cold, a mere semblance of what had previously been an active rash.

When medication was begun several days after the onset, the rash fully developed and having existed for a day or two, the action of the drug was somewhat more intensive. A mild reaction took place in which all existing symptoms were temporarily accentuated—the rash appeared more reddened, the glands when already affected became more swollen and the temperature and pulse higher. Following this temporary reaction all symptoms rapidly cleared away resulting in greatly shortening the duration of the disease, protecting the heart and preventing complications.

As a prophylactic, when contacts were given moderate doses scarlet fever never developed during the period of medication, though in some cases a chronic infected throat would react mildly to the drug—a reaction occurring even in an average individual when taking the drug. So repeatedly and uniformly were the above phenomena observed that the belief that iodine was antitoxic and antimicrobic in scarlet fever seemed justifiable and its use was advocated in the first report upon the drug.

The question of kidney irritation was always uppermost but apparently without foundation. Albuminuria following cases of scarlet fever treated without iodine were completely cleared by subsequent iodine medication in a comparatively short time. The scarlet fever toxin is the irritative factor and not the iodine radicle which must be both antitoxic as well as antimicrobic in order to produce such specific action and results.

While the iodine treatment of scarlet fever has proved exceptional in my series of cases (in private practice) throughout a period of over nine years, it was a difficult matter to formulate a concrete detailed or comparative report that would be of scientific value.

On July 25, 1925, with the permission of the director, Dr. S. S. Woody, a control test was started at the Philadelphia Hospital for Contagious Diseases, the results of which were completed on November

28, 1925. The complete report includes "a synopsis" of each of the two hundred cases from which in turn the summaries and tables were compiled. For the sake of brevity, only the summaries, tables and conclusions are herein included.

With the exception of giving the information relative to dose, action and reaction of the drug, I took no part in the hospital corroborative test.

Prior to beginning the test at the hospital and in order to be definitely certain that no untoward effects might result to the little patients, I personally took four and one half ounces of the iodine preparation "at one dose" and this, without having previously taken any of the preparation in order to raise tolerance. (The equivalent is more than six ounces of the tincture of iodine or two hundred and sixteen grains of elementary iodine.) The results were a feeling of fullness in the head, a metallic taste in the mouth, flushed skin, slightly increased pulse and respiration, and frequent urination, followed within sixteen hours by two loose bowel movements with normal general condition within twenty-four hours. For several days after, the urine responded to the tests for iodine, but not the slightest semblance of kidney irritation, albuminuria or other untoward effects. With the toxicity and kidney irritation factors eliminated or within a wide margin of safety, the test was carried out at the hospital and the essence of the report is given below.

The cases recorded in this report were all definitely diagnosed and the more severe types were selected for colodine treatment. Standard doses were adopted without consideration of age and only slight modifications were made at different stages of the disease.

The aim was to get rapid saturation with the drug and then to taper off gradually as the acute symptoms subsided. However, in order to determine the action and value of the drug at different stages of the disease, colodine was administered beginning at various periods from day of admission and at times in different doses.

By the term full colodine medication is meant as follows: First day one dram every fifteen minutes to one hour (eight doses); second day one dram every hour to two hours (eight doses); third day one dram every two to three hours (eight doses); fourth day one dram q. i. d.; fifth day one dram t. i. d.; sixth day one dram b. i. d.; seventh day one dram or one half dram b. i. d. till end.

This scheme of dosing was carried out in the fourteen months old patient as well as the adult, with slight variations at times.

All complications listed in the following report such as otitis, adenitis, and mastoiditis were not recorded unless they were suppurative in character.

The data in the accompanying tables show in detail the results of this comparative test.

CONCLUSIONS ON THE ACTION AND THERAPEUTIC VALUE OF COLODINE IN SCARLET FEVER

The unusually small number of complications and their mild character, together with the total absence of house infections in the cases treated with full colodine medication fairly early, can be explained only by the fact that the drug increases the resistance and stimulates the fighting powers of the body against the infection.

TABLE I.—SUMMARY OF ONE HUNDRED CASES OF SCARLET FEVER TREATED WITHOUT COLODINE (CONTROL).

100 cases admitted from April 3, 1925, to November 8, 1925, inclusive

Mild	74 cases	Average time in hospital per case: 53 8/9 days (not including 4 that died).
Moderate	14 "	
Severe	12 "	

Complications—47

Otitis	22
Nephritis	3
Febrile albuminuria	1
Adenitis	3

Since no toxic phenomena were noticed by any of the medical staff at any time during or following the administration of the drug, and in view of the large doses employed (one fluid ounce daily for three or four days in succession), colodine appears to be non-toxic.

In spite of the fact that massive doses of iodine or its compounds are contraindicated in diseases with a tendency to kidney irritation, no kidney complication of any kind was caused by the administration of full doses of colodine. In fact, cases showing signs of kidney irritation before the drug was given cleared up rapidly and completely under the colodine.

Colodine did not show any special effect upon the heart except that of mild stimulation. Patients under colodine seemed to tolerate their condition much better, and appeared much brighter and less toxic.

As far as reactions are concerned colodine started on the first day of admission in fairly early cases, produced a mild reaction—slight accentuation of the rash, higher elevation of temperature and only moderately increased enlargement of tonsils, cervicals and sometimes other glands—all of which subsided within a few days. Continuation of moderate doses cleared the case without any subsequent return of symptoms.

Colodine started later when complications are already in evidence—bull neck, large tonsils, etc., with no elevated temperature but generally low fighting power—produces a rather abrupt, powerful reaction, greatly accentuating every existing symptom. The bull neck or other glands affected become enormously enlarged and hard, continuing to increase in size and hardness to an unusual degree. The temperature suddenly shoots up and the entire picture is changed from a dormant nonreacting condition to one of extreme acuteness. However, with gradual reduction in the doses after a few days of intensive medication, all symptoms gradually subside, and it is remarkable that such enormously enlarged glands rarely go to the point of suppuration. When there is already formed a suppurating point in the gland, a similar marked reaction occurs resulting in a great increase in swelling and hardness, but with reduction of medication all swelling is resolved, leaving only a fluctuating area. When this area is incised and the pus evacuated, healing takes place in a much shorter time than usual, especially if moderate medication (one dram t. i. d. or b. i. d.) is continued. It seems as if the infectious bacteria in the tissues involved are suddenly attacked by the iodine laden body fluids resulting in an immediate response and that all the bacteria floating in the blood stream are entrapped within the enlarged glands and are either rapidly destroyed or result in a sort of fixation abscess, a desired feature in scarlet fever since it is a streptococcal infection.

An analysis of the above report clearly shows the value of iodine in the treatment of scarlet fever. Not one but all factors are favorably influenced to a degree not as yet attained by any other form of treatment.

	Urine	*Showing albumin, casts or both*	
100 cases Control	Mild .....74 cases	7 cases	9.5%
	Moderate ....14 "	6 "	43. %
	Severe .....12 "	3 "	25. %
Iodine treated 100 cases	Mild .....32 "	2 "	6.2%
	Moderate ....45 "	7 "	12.6%
	Severe .....23 "	5 "	21.7%

DURATION

The duration or hospital stay has been greatly shortened especially in the early iodine treated series. The average short period a scarlet fever case is kept in this hospital is about five weeks, irrespective of its mildness, therefore the greatest difference is noticeable in the moderate and severe types of cases.

	Average time in Hospital:	Shortened by:
Control 100 cases	Mild ..... 43 2/3 days	
	Moderate ..... 76 "	
	Severe .....109 5/8 "	
Iodine treated 100 cases	Mild ..... 43 "	2/3 days
	Moderate ..... 54 2/5 "	21 3/5 "
	Severe ..... 69 "	40 5/8 "
Early iodine treated 69 cases	Mild ..... 42 "	1 2/3 "
	Moderate ..... 47 7/10 "	28 3/10 "
	Severe ..... 48 "	61 5/8 "

COMPLICATIONS

In both the control and iodine treated series no complications occurred in any of the mild cases. The tables below are based only on the moderate and severe types of cases.

1. Control 26 cases	Complications 47	.....180.7%	
2. Early and late iodine treated 68 cases	Total complications 55	.....	80.9%
	During medication only.... 6	.....	9. %
3. Early iodine treated 43 cases	Total complications 11	.....	28. %
	During medication only.... 4	.....	9.3%

Table II shows a high percentage of total complications because this series recorded forty complications before the iodine treatment was begun. Most of the late iodine treated cases were started just as a complication threatened or had already appeared, in order to determine the preventive or abortive power of the drug. In other instances it was used to hasten clearing of a long existing complication.

Excluding the complications that existed before medication was started and those that occurred after it was stopped, the actual decrease is from 180.7 per cent. to 9 or 9.3 per cent. It is generally known that within five days after iodine medication is discontinued almost all of the drug is eliminated from the body no matter during how long a period it has previously been taken. It is therefore reasonable to deduct or exclude complications occurring after the five day period.

With intensive medication started earlier (as is possible in private practice) and continued longer after the acute symptoms have subsided and the average complication period passed, the 9.3 per cent. complications would be greatly lowered, a result not as yet shown by any other form of treatment.

In view of the evidence contained in this report I believe that colodine is deserving of a high place in the specific treatment of scarlet fever and may or may not be combined with the serum in severe cases.

In carrying out this work I wish to express my appreciation to the medical director of the hospital, Dr. S. S. Woody, and to his first assistant, Dr. H. Tucker, who gave me the opportunity to conduct this work, as well as to Dr. Hirata, Dr. McLaughlin, Dr. Noyes, Dr. Conaway, and Dr. MacMurray for their kind assistance.

2415 North Fifty-fourth Street.

Neurasthenia and Allied Neuroses: Symptoms or Diseases?

The Value of Neurocirculatory Tests

HAROLD WALGROVE WRIGHT, M.D.

Foxboro, Mass.

There are few, if any, symptom complexes more difficult of understanding completely and feeling sure of as to cause and pathological sequence than the symptom complex which we, either in despair or impatience, are apt to label with the socalled term neurasthenia or a neurosis.

Granting that perhaps the majority of people who present the neurasthenic or the anxiety syndrome in the absence of any obvious disease, are constitutionally and primarily inferior in their physical, and hence their nervous or personality makeup, they have nevertheless got on fairly well with themselves as they are, and have kept away from the doctors until some additional stress of either a physical or psychological sort has produced feelings and incapacities which bring them to us. There has been some point of departure from their average.

Let us consider what this point of departure may be due to; on what level of functional activity and in what category of pathology has the divergence from normal health occurred?

For convenience we may classify causes and hence pathological condition into:

1. Definite physical disease entities producing a variety of symptoms of the neurasthenic or neurotic type.

2. Habit factors or physiological causes: in respect to mode of life—eating, sleeping, working, drinking, smoking, playing or not playing at all.

3. Psychological causes: The personal situation in life, e. g., marital, troublesome home affairs, unsatisfied affections, a distasteful occupation, an uncongenial social environment, lack of friends to unburden oneself to.

4. Early stages of definite psychoses—general paralysis, manic depressive, schizophrenic, involutional psychoses.

All of these and more can produce what is commonly called nervousness. Indeed about all that the patient in many instances volunteers, in speaking of his symptoms, is the word "nervous."

So we are obliged to get first of all a good history. This means a history which shall embrace the whole individual considered as a unit composed of physical, environmental and psychological components. This means that we must get an account of all past illnesses, their symptoms and their results; also a history of the personality in his reaction to his past and present environment, his past and present difficulties of an industrial, domestic and intimately personal sort. The method of getting such information must be an orderly biographical one and, naturally, we must know what to ask about, while at the same time we keep our minds free from any preconceived theories as to the cause of nervous symptoms.

We must know what to ask questions about. But it is easy to overlook something unless we have a definite scheme or at least have a few outstanding subjects or items that are covered in every such interview. The same remark applies to the physical examination which follows, by which we aim to elucidate special symptoms complained of, either by exclusion or positive findings.

As history taking proceeds many symptoms other than the socalled nervous will be brought out. For instance, we will be told that the heart palpitates, the bowels are constipated, there is pain around the heart, feelings of faintness with or without exertion, flatulence, insomnia, night sweats, inability to eat the average meal, feelings of vague fear as if something awful was about to happen; feeling of being tired all the time, especially in the morning and in spite of enough sleep; unpleasant dreams; tinglings and achings in the limbs, inability to make decisions, special phobias, and other conditions.

What definite items in the history and the physical

examination under the first heading of physical causes should be especially covered? Tuberculosis comes first to mind because many people previously diagnosed as neurasthenic turn out to be tuberculous. Malaria also must be considered. Disorders of the thyroid such as mild or masked hyperthyroidism and hypothyroidism; focal infections of tonsils, teeth, sinuses, which so often produce neurocirculatory defects and hence the syndrome of fatigue and palpitation and a generally socalled run down state, or a mild hyperthyroidism. Nephritis with hypertension or sometimes with a low blood pressure and secondary anemia can give the same syndrome. Syphilis, particularly cerebrospinal syphilis, may be entirely responsible. Pernicious anemia also comes in for consideration when paresthesias and fatigue and vague digestive disturbances are complained of. Intestinal amebiasis is productive of a train of symptoms of a neurasthenic nature.

In the second category of possible causative factors, i. e., the habits and mode of life, we should bear in mind the fact that many people are living at high pressure; not because they need to but from habit only. People easily get the hurry habit and this habit involves all their activities. In other words, they have either never acquired or else have lost a normal degree of poise and deliberation. They do not know how to relax. They may have social or other ambitions far beyond their capacities and be in a hurry to fulfill them. Such a state leads to fatigue and unrest and the desire for artificial aids and hence they may smoke or drink coffee and alcohol to excess. What such people need is to have somebody point out to them the ridiculousness of their mode of life and show them how they can live and work to better advantage. A little philosophical reading, and saving some part of the day for quiet thinking and for being alone is often indicated.

With respect to sexual habits as productive of neuroses a word should be said about the relation of frequently aroused but incompletely gratified sexual desires. An anxiety type of neurosis in which vagotonic symptoms such as globus, pylorospasm, spastic colon, palpitation and sweating, general uneasiness and as time goes on a vague fearfulness, can all be the result of either coitus interruptus or, in the case of unmarried people, of frequent social contacts without complete physical relations. Such symptoms are apt to become chronic and last even after the cause is removed if the cause has been operating frequently in the past.

There may be an intricate psychological mechanism back of any neurosis and much time is necessary to bring it into light. It is not possible to cover this phase of the subject in this paper. But there are certain specific psychogenetic symptoms which stand out as guide posts when taking a history and after a physical examination has excluded reasonable physical causes. Of these specific symptoms, I would first mention fear. The fear may be just vague fear of nothing or, by further analysis we may find it is a fear of some particular thing or of doing some particular thing, e. g., fear of going out on the street, of riding in elevators or ferry boats or trains. In my experience fear, either vague and general or specific fear, is most often simply a symbol of indecision about something of personal import to the patient's immediate future or present situation. The fear of being alone, for example, is often due to the fact that when alone the matter that the patient is undecided about keeps recurring to mind again and again, and this is relieved or prevented by being distracted in the presence of others, but of course not cured thereby. The fear of going out or of getting on a ferry boat or train or elevator may, to be sure, be the result of some previous experience of a fearful nature in respect to ferry boats or trains or street cars and so be simply the result of suggestion; but we must not overlook the fact that there are and have been such fears without such causes, and that when these cases have been thoroughly analyzed we have found that the fear was a defensive and compensating symbol. In other words, the patient had a more obscure but still very definite reason for not wanting to take the customary boat or train or to go out at all; and, rather than admit to himself or herself that they did not wish to go on playing the game, they have fooled themselves into believing that they were afraid of taking the steps that were necessary to bring them again into the place where work or some other social contact had become unpleasant and distasteful to them because of some particular experience there. Such fears are properly called hysterical.

With regard to the vague general feeling of fear, I would repeat that this is likely to be due to being in a state of indecision regarding making some definite change in life, such as a change of employment and location. There is a desire to make the change and also a desire for other reasons not to make it. The choice is free either way and the responsibility for making a choice is entirely up to the patient. If it were not there would be no indecision and hence no fear. After weighing matters pro and con for days or weeks, such a patient becomes fatigued, sleeps poorly, loses appetite and digestive powers, suffers from feelings of pressure in the head and indeed may have an increase of blood pressure, which is not surprising when we recall that disturbing and fearful emotions produce excessive action of the vagus and the sympathetic nerves and the endocrine glands.

Such conditions may be the result of indecision of character to begin with, I grant, but even so, the illness which occurs from indecision is not present so long as the individual moves along in the same rut or routine of life as hitherto; for it is only the indecision about matters of real importance to their careers that produce serious symptoms in indecisive characters. In such cases the physician or someone else may have to do the deciding for the patient. At any rate, it is interesting to note that as soon as a decision is made and acted on, all the distressing symptoms disappear as if by magic. I have seen this happen time and time again. There may be left over a "crying over spilt milk" sort of syndrome with reactionary depression, no matter how the decision is made; but this is temporary and far easier to endure than the anxious, restless state that accompanied the stage of indecision. For after all, things do work out somehow and somewhat to our satisfaction providing we make some definite step.

The early stage of any psychosis of a chronic type may be manifested by symptoms of a neurasthenic, simple depressive, or anxiety neurosis type. This is particularly true of the early stage of manic depres-

sive psychosis, dementia precox and general paralysis. In addition to the fatigue syndrome in the early stage of a manic depressive psychosis a little questioning will bring out a more marked degree of anhedonia or general distaste for all customary interests, a feeling that nothing is worth while, a loss of enthusiasm and interest in any form of pleasure, an indifference of the affections toward relatives without any specific cause; this sort of mood may be alternate with a short period of mild overactivity and brief elation or euphoria, sleep being less than normal. Such alternate moods may exist for many months before the psychosis becomes acute.

In the early stage of dementia paralytica a mild depression combined with anxious, restless feelings, without any delusions or extravagant behavior and with a certain amount of dulling of mental activity, manifested by absent mindedness, attention disorder and lowering of the esthetic or moral sense quite foreign to the patient's nature may be the only symptoms for a long time. However, it is not unusual to note that in this early stage the speech is somewhat affected. This can be easily overlooked unless definite test phrases are given and the slight slurring and tremor listened for in the replies. The handwriting may show occasional omissions of letters and punctuations. All of these symptoms may exist before any change is found in the pupillary reactions or other reflexes.

In the hebephrenic type of dementia precox, an early diagnosis from neurasthenia or psychasthenia is sometimes impossible. However, in hebephrenia there occurs before long a change in the patient's appreciation of his responsibility toward others, a loss of conscientiousness, an inability to put up with the ordinary difficulties of most jobs, a flitting from one position to another as soon as any difficulties arise, in entire disregard for obligations incurred. Later, as the psychosis progresses, all work or attempts at work are given up and the patient withdraws into himself to live with his phantasies or daydreams. Before this occurred, he had been as open a personality, as accessible to interview and apparently as sane as the "neurasthenic." In both the sane neurasthenic and in the hebephrenic, there will be found the cold, clammy and cyanosed extremities, the exaggerated reflexes, the visceroptotic habitus and other signs of constitutional inferiority; so a physical and neurological examination does not help us in differential diagnosis. Time alone may tell the true story; but a careful history dealing with the whole course of the disorder and with the biography of the patient can be quite helpful. For example, in ordinary neurasthenia which is not due to any other disease entity such a history is apt to reveal that one patient has always been more or less asthenic, while another who is developing dementia precox has been up to the average in health and efficiency until recently.

Have we any way of distinguishing a true asthenia of the nervous system from an imaginary fatigue or from a malingering of the fatigue syndrome? This becomes an important question in dealing with industrial insurance cases, government pensioners and post-traumatic cases.

Let us suppose in a given case that the physical history and the physical examination have failed to reveal any reasonable causes for the complaint of fatigue and inability to do the customary day's work, that the psychological aspect of the individual is negative and that no environmental causes of an emotionally disturbing sort have been found. Can we go any further in the objective examination before saying that there is nothing the matter?

In the United States Army a great deal of research has been done on the effects of aviation upon a selected group of normal men, as well as on the suitability of recruits for the aviation corps. Aviation, particularly in time of war, is a nervous stress of an exceptional type. Not only must the apparatus of equilibration be perfect, but the circulatory system must be at all times efficient. In connection with the latter system, I would point out that the efficiency of the circulation of the blood and the response of the nervous system to the variable demands upon the circulation, the two being inseparable, comprises all that we call physical efficiency. In the last analysis, normal neurocirculatory function spells normal efficiency, at least so far as physical effort is concerned; and we might add that the same is true of mental efficiency in accord with the degree of mental development. All cells are dependent upon the reception of a healthy blood supply and an excretion through the blood of their waste products for normal health of those cells; and back of all this is the great complicated nervous system which is the main spring of everything else and through which all metabolism and secretory and motor functions are performed.

The need of a measure for physical efficiency whereby degrees of fatigue, physical fitness, and health may be determined has been felt alike by the medical profession, physical educators and school hygienists, and when we are dealing with those who may be either malingering or who only fancy themselves ill, the need is still greater.

The tests to be discussed have little to do with functional heart measurements, although they point out, when analyzed separately, some of the factors pertaining to functional efficiency of the heart. But they are measurements particularly of the efficiency of the nervous system and particularly the vasomotor and sympathetic nerves.

It is well known that the pulse rate is an indication of health, and that the rate is slower in well trained vigorous men trained for muscular work. It is also a matter of agreement among physiologists that the rate of the pulse according to the posture of an individual has significance. Meylan, a physical educator of large experience, has concluded that a pulse rate of forty to eighty in the horizontal position and a rate of fifty to ninety in the standing posture are favorable signs.

All available evidence indicates that with improvement in physical fitness, the heart beats less frequently and more efficiently, and it follows that the pulse rates in the reclining and standing postures may give useful hints about the degree of fitness and health. A change in rate from the average may not be shown in both postures, but only after assuming the standing posture. The increase of rate in the standing posture as compared to the reclining posture has been found a useful index of fitness.

It is also well known that the pulse rate after exercise is comparatively slower in a healthy and well trained man than in an untrained person. A widely recognized and used test is the time required for a

pulse rate to return after exercise to its previous rate.

The arterial pressure at rest offers little information of value as to the condition of a young person free from hypertension, and various investigators have found that the degree of training of an athlete has little effect upon the reclining blood pressure.

The hydrostatic effects of posture and the manner in which the splanchnic vasomotor mechanism compensates for this is well known. When a person changes from the reclining to the standing position, the splanchnic vasomotor tone overcompensates the effects of gravity. In normal subjects, the systolic pressure is about ten millimetres higher in the standing posture. That the systolic blood pressure falls on assuming standing posture in individuals weakened by disease, overwork, dissipation and lack of sleep has been recognized by Crampton. He demonstrated that a subject when standing might show weakness by a decrease in the systolic blood pressure or by a large increase in the pulse rate.

TABLE I.

POINTS FOR GRADING CARDIOVASCULAR CHANGES

A. *Reclining pulse rate*

Rate	*Points*
50- 60	3
61- 70	3
71- 80	2
81- 90	1
91-100	0
101-110	—1

B. *Pulse rate increase on standing*

0-10 *beats, points*	11-18 *beats, points*	19-26 *beats, points*	27-34 *beats, points*	35-42 *beats, points*
3	3	2	1	0
3	2	1	0	—1
3	2	0	—1	—2
2	1	—1	—2	—3
1	0	—2	—3	—3
0	—1	—3	—3	—3

C. *Standing pulse rate*

Rate	*Points*
60- 70	3
71- 80	3
81- 90	2
91-100	1
101-110	1
111-120	0
121-130	0
131-140	—1

D. *Pulse rate increase immediately after exercise*

0-10 *beats, points*	11-20 *beats, points*	21-30 *beats, points*	31-40 *beats, points*	41-50 *beats, points*
3	3	2	1	0
3	2	1	0	0
3	2	1	0	—1
2	1	0	—1	—2
1	0	—1	—2	—3
1	1	—1	—2	—3
0	1	—2	—3	—3
0	0	—2	—3	—3
—1	0	—3	—3	—3

E. Return of pulse rate to standing normal after exercise.

Seconds	*Points*
0-30	3
31-60	2
61-90	1
91-120	0
After 120: 2-10 beats above normal	—1
After 120: 11-30 beats above normal	—2

F. Systolic pressure, standing, compared with reclining.

Change in MM.	*Points*
Rise of 8 or more	3
Rise of 2-7	2
No rise	1
Fall of 2-5	0
Fall of 6 or more	—1

Normal Score: 10-18

According to the method of Schneider referred to above, the patient should recline on a couch for five minutes and get well relaxed. The pulse rate is then counted for a full minute and recorded. The systolic blood pressure is then recorded. The patient should then stand upright for two minutes and the pulse then counted for a full minute. If the pulse varies during quarters of a minute its rate when the same for two quarters should be recorded as the rate per minute. The blood pressure in the systolic phase should then be recorded. The patient is then told and shown how to step upon a chair about eighteen inches from the ground and down again five times in fifteen seconds, and at the end of the fifteen seconds of exercise the pulse rate is recorded. The pulse is again counted after thirty seconds from the time the exercise was finished, and if it has returned to the previous standing rate, the test is finished, otherwise the pulse rate is counted at the end of sixty, ninety and one hundred and twenty seconds. If still above the previous standing rate, the number of beats above this rate at this time is recorded. The score is then figured out from the table. A score of nine or below is considered abnormal by Schneider, because in every such instance he found that there was something definitely wrong with the patient, either focal infection or other debilitating disease, or fatigue.

There follows a brief summary of scores obtained in this test. While the results in these cases are in some instances not what might be expected, in other instances the results are quite consistent with what has been said about the adequacy of the neuro-circulatory function as an index of good health.

Thirty-one men were tested. All of these were referred because of some symptoms thought to be associated with functional derangement of the nervous system. The prevailing complaint was fatigue.

Fourteen of these patients had a negative physical status. Eight had significant focal infections. Two had had the operation of thyroidectomy. One had a secondary anemia. Two had had fractured skulls. Three were constitutionally inferior in physique to a marked degree. One had valvular heart disease.

1. In the fourteen cases with no physical findings there were ten with normal scores and four with scores below normal; of the latter one had had mumps complicated by bilateral orchitis, one was working both day and night, one was without apparent etiology and one had had influenza.

2. Of the postoperative hyperthyroid conditions, one had a score of 5, the other was normal and felt perfectly well while taking thyroid extract.

3. Of the eight cases with focal infections, five had subnormal scores, one as low as 1, two as low as 3, one 7, one 9. Three had normal scores.

4. The one case of secondary anemia which followed influenza had a subnormal score of 5.

5. Of the two cases of intracranial trauma following head injury one had a score of 9, the other a score of 3—both subnormal.

6. Of the constitutionally inferior cases, one just passed, the other two were subnormal.

7. The one case of valvular heart disease had a subnormal score of 7.

Total number of subnormal scores 16, total normal scores 15 of which ten would have been expected, and five are not explained.

Neurosis and Total Personality*

FRANZ ALEXANDER, M.D.

Berlin

(*Concluded from page* 210)

The repressed pushes itself powerfully in its original form because the pressure is over great and because the efficacy—one may say—takes away the moral appearance of the inhibiting agency because of the suffering which it causes. One may also express it thus—that the mentality, the judicial spirit, with which the guilt conflict is freed is the foundation of the neurosis. In the sentence that the guilt is destructible by punishment, by suffering, is contained the nucleus of the entire neurosis doctrine. Through selfpunishment, through suffering, the neurotic soul acquires the possibility of holding fast to the objects given up by the ego, yes, to the pregenital aggressive fundamental position. Every such regression into the sadistic leads then to an inculcation of the sense of guilt, which demands new suffering and so the neurosis formation makes always greater advances with a mechanism similar to that of an uncompensated heart lesion. This also explains why the neurotic patient clings so tenaciously to this autonomy of internal legislation and consummation of punishment.

In this spirit of its conscience it can hold fast to the primitively condemned tendencies, it takes the punishment, the suffering on itself and needs to retain that for which it feels guilty.

Hence the analytical cure is not closed when the subject becomes conscious of his repressed content. The patient must also renounce his requirement for punishment, must give up the primitive spirit of his inner court of justice. So long as the mechanism of payment of his guilt functions through suffering, the way to new symptom formation is still open, however extensive the sense of the individual symptoms may be uncovered. Not only the content sense but the sense of the symptom formation must become known.

Recovery from a neurosis therefore signifies a radical alteration of the spirit in the inner régime of the personality. So long as feelings of guilt may be freed by selfinflicted punishment or through punishment in general and the suffered punishment, often however masochistically pleasurable suffering, justified to the formation of new symptoms, the basis of the neurosis is at hand. Symptoms do not become cured but the neurotic spirit in its total psychic housekeeping; which is comparable with that of the tutor, who believes it sufficient to decree a penalty of his pedagogic duties. As we know the origin of the superego from the period of education, it lies near to bringing not only the education but also our present day punishment justice into an original association. The relations presented between the parts of the psychic apparatus when laid bare allow themselves to be formulated as a pure economic code. Such a formulation will certainly be welcome to those who from a certain piety, follow the material way of thinking in which we are all brought up, with surprise at such a far going psychological reconstruction of the personification of the psychic constituents. Before all we must modify our old tried dynamic sentence, in its nature still valid, that the psychic processes are compromise performances between ego righteous and ego foreign impulsive tendencies, to this extent that we substitute superego righteous for ego righteous; whereby account must be taken of the unconsciousness of the actual moral requirements, to the unconsciousness of the repression. We assume here two great unconscious centres of force in the psychic apparatus, the energy of direction of which is opposed; the impulsive, pressing according to the motility—the centrifugal tendencies of the it and the centripetal inhibitory tendencies of the repressing agency with moral and masochistic content. This second centre of force may be comprehended as the continuation of the moral pressure of society in the interior of the ego, as a phenomenon of adaptation to selfmade culture. Every process in the interior of the apparatus is subjected to both manifestations of force. And now we see that in the neurosis no stationary equilibrium exists, but simultaneously or alternately both a strengthening of the centripetal pressure—meaning the overmorality of the neurotic—as also as a reaction to the strengthening of the centrifugal tendencies of it, which comes to expression as a return of the repressed. And conversely we see also the reciprocal process as the eruption of the repressed again effects a reactive intensification of the punishment tendency. One may also express this phenomenon thus: that in the healthy from the mixture of both of these directions of energy a third, qualitatively new, tendency forms itself, which we term sublimation, that is, a domesticated impulse with action directed externally; with the neurotically diseased subject on the other hand the original unmodified tendencies remain side by side, on the one hand with crude masochistic and on the other with primitive and ego foreign content, which reciprocally consume each other in their endless to and fro swinging. The result—the neutrality of the neurotic externally.

This presentation leads to a revision of our ideas on symptom formation. Our previous conception was this, that the symbolic or other disguise of the hidden sense sufficed to explain the symptom formation. We see now that there is necessary another important factor, namely, the weakening of the agency of repression which I have sought to present to you today. The nature of this weakening consists of the fact that the superego sacrifices the efficacy of its performance of repression through the shallow punishment system with which it has substituted its impulse regulating and repressing task. With the decreeing of punishment it has fulfilled its duty and may now close its eyes to the pressure of the it. If we are serious as to the unconscious char-

*Read before the IX International Psychoanalytic Congress, at Homburg, September 3, 1925.

acter of the repression it must at once be apparent that the disguise of the latent sense cannot suffice to account for the symptom formation. The disguise of the sense is of importance only for consciousness and serves to protect the condemned tendency from the denial of the conscience ego. For the unconscious censure, for the actually repressing agency, disguise is without significance. The best proof is that despite disguise of the sense feelings of guilt appear. The repressing agency knows the language of the unconscious and does not allow it to go astray. It demands punishment for wishes which only appear in consciousness disguised. Without the assumption of an unconscious moral agency which has a direct feeling for the unconscious, the unconscious requirement for punishment cannot be explained, and this agency is not to be led astray by mechanisms of disguise, it must be bribed with suffering. An almost experimental proof of this, how great economic significance in the symptom formation the feelings of guilt and selfpunishment possess along with the disguise of the sense, is often furnished by a frequent phenomenon of the treatment, which ought to be known to most psychoanalysts: I mean a sort of transitory negative therapeutic reaction. Then the work of interpretation makes good progress, the sense of the symptom or the transference situation is brought to light in a particularly convincing manner, there often appears —perhaps almost in every case—a period in which the patient apparently applies himself with all remedies against himself, as for example through repeated misbehaviors which could often lead to severe corporeal injuries, or again through occupational errors or even with psychically conditioned organic disease. One gets the impression that if the patient would answer obstinately to our explanations of the ego foreign portion of his person: "I believe it, it is just correct that I am such an abandoned subject, but I punish myself properly for it and you cannot have any further advantage over me."

Inescapably at the close of these considerations a problem forces itself, which hitherto has been treated by psychoanalysis in stepmother like fashion; the problem of health. We are aware that all of our actions are in the last end expressions, even if modified expressions of the it; that all of our sublimations originate in the Œdipus complex and today we see that the repressive instance is not to be deceived over this point. It recognizes the best disguised smuggled ware and exacts a custom duties therefor. How comes it that the sublimations excite no feeling of guilt over the socalled normal actions; that we do not have to pay for these with suffering? Or the question may be formulated from the viewpoint of therapy: How is the alteration in the impulsive life which we, or better the patient's conscience demand of him, how shall the impulsive life be so shaped as to excite no sense of guilt? It is clear that the conscious ego which represents the point of view of reality must be carried through. We have, however, said nothing of the content. You see that this question signifies nothing other than the psychology of morals. Freud has already said the essentials on this subject—that the content of the neuroses will change with the alteration of the moral concepts of society. Hence there is not much to say here of content. The content of the ego righteous alteration of the impulsive life is dependent on the prejudices and convictions, in short of the stages of organization of society, and goes no further than the actual non-psychological problem of therapeutics. Though often there, where the therapeutist arrested in the practical aim ceases to inquire, begins for the naive curiosity of the investigator the most attractive of the problems. Allow me, if not to solve this problem, at least to illuminate it. For the unsublimated impulsive life the answer is easy and known to us all; we ever see again that the attainment of the genital stage, the positive—erotic—relation to the object and indeed to the exogamous object, signifies the freeing from the sense of guilt and the approbation of the deepest unconscious strata of the conscience. Less simply does the question answer itself in the realm of the social relations, of sublimations. Following the incitation of Freud, Sachs has sought, with a valuable sequence of thought, to solve the problem for the art of poetry. According to his comprehension it is the social element which differentiates poetry from phantasy, and it is just this social element, the imparting to others, the overstepping of the limitations of personality, which abolishes the sense of guilt; the fact of the action on others in the positive sense. I believe that this idea has a much more general validity, is not limited to poetry but holds good for every cultural accomplishment, for every sublimation which has a social relationship.

When Rank speaks of a biological sense of guilt which represents the claims of generations I would attribute to the social conscience, which is more readily comprehended psychologically, the task of watching over social behavior and sublimated impulse life, since it harmonizes with erotic relations and reacts on the destructive with feelings of guilt. In the sense in which Abraham speaks of the genital character, we may also speak of a genital stage of social behavior. And in fact we see in the inhibition of production in the artists, how the interest which should count in the work is replaced by other things with greater narcissistic coloring, as competition, prestige, technical hairsplitting, sense of inferiority, etc.; just as the genital coloring of production is obscured by the symptom complex of the father conflict. The social deed silences the sense of guilt and has a similar economic rôle in the healthy as suffering does in the neurotic patient. The neurotic, however, pays with a coin of narcissistic value, with suffering from which he can draw masochistic pleasure; while the socially directed act is a performance of energy which is for the benefit of others. The newly created work upon which territory it is supplied, presents the new life, the creation of Eros, for which the primitive crime is forgiven. I must think here of the motif of Tannhäuser, which recurs in an African novel of the Froebenius collection, in its most original sense. The judge forgives the murderer who had committed incest with the condition that the dry branch with which he had killed—the symbol of the destructive impulse laid bare by Eros —must put forth new twigs. In this judge's law is contained the primitive law of human conscience; the extinguished life can be expiated only through new life. And corresponding to this law the Eros impulse follows the destruction impulse, to mingle with it and make good its destruction.

Practical Therapeutics

A New, Nontoxic Analgesic and Antirheumatic Drug of Definite Value in Vascular Hypertension

EMANUEL W. LIPSCHUTZ, M.D.

Brooklyn

The experiments reported in this communication were conducted for the purpose of determining the pharmacological activity and therapeutic value of a new drug, expuralgin. The plan was to subject this drug to a rigid scientific test by carefully controlled animal experiments and accurate clinical observations.

The toxicity of expuralgin was investigated by means of intramuscular injections in rabbits. Further tests for a possible depressant action were carried out on human subjects. The effect of its use on the uric acid metabolism was carefully investigated. Repeated clinical observations were used to gauge its analgesic effects. Very significant was the influence of expuralgin in vascular hypertension. These topics will be discussed in detail in other sections of this paper.

NATURE OF EXPURALGIN

Expuralgin is a new preparation. Chemically, it is potassium magnesium acetyl citrate.

TOXICITY

In studying the toxicity of expuralgin, four rabbits, weighing five pounds (2488 gm.) each were injected intramuscularly with a sterile solution of the drug in a dose of fifteen mg. per pound of body weight. Injections were made on two occasions, at weekly intervals. The animals were not injured in any way and suffered no apparent toxic symptoms. In terms of body weight, the dose given to the rabbits would be equivalent to a dose of thirty-five grains of expuralgin at a single dose for a man weighing 150 pounds. Therefore, it may be stated that expuralgin failed to evince toxic symptoms in rabbits when given intramuscularly in three and a half times the therapeutic dose by mouth.

TESTS FOR DEPRESSANT ACTION

In this experiment, eleven normal subjects were tested before and after medication with expuralgin, in order to determine whether this drug has any depressant action when given in therapeutic doses. One of the subjects had hypertension but was otherwise normal. The drug was given in doses of ten grains (0.65 gm.) every two hours for six doses. Observations were made before and after medication on the following phases of physiological activity: pulse rate, respiratory rate, systolic and diastolic blood pressure, total leucocyte count, and percentage of polymorphonuclear cells.

The results of these experiments are given in Table I. From a study of the table it will be apparent that expuralgin has but slight effect on the pulse rate, respiration, or blood pressure of the normal subject. It is true that the average figures showed a slight drop for all of these readings, but no more than could be accounted for by pure chance. The difference in the readings before and after medication was too slight to receive any significance. In the one patient with hypertension, there was a pronounced drop in the blood pressure following expuralgin medication. This matter will be discussed in another section of this paper.

With regard to the leucocyte counts, the comparative readings before and after medication showed a marked change. In nine of the eleven cases, the leucocyte count was increased after treatment with expuralgin. The average readings showed a rise from 8820 to 11363 white blood cells after expuralgin medication under the conditions of this experiment, quite a definite increase. The percentage of polymorphonuclear cells was slightly reduced; but in view of the higher total white count, the actual number of these cells was definitely increased.

TABLE I

TESTS FOR DEPRESSANT ACTION

	Before Expuralgin[1]					After Expuralgin

[1]Ten grains (0.65 gm.) every two hours for six doses.

This induction of artificial leucocytosis is probably, to some degree, responsible for much of the therapeutic potency of expuralgin in relieving local inflammatory conditions. The fact that local affections are usually favorably influenced by general leucocytosis is well known. Ferguson and Thomas (1) in 1925 showed that artificially induced leucocytosis is remarkably beneficial in a variety of local disturbances, including trachoma, furunculosis, small infected wounds, arthritis, bronchiectasis, acute otitis media, iritis, iridocyclitis, and carbuncle. Their method of induction was by means of injections of mercury salicylate. Elliott (2) in 1925 obtained similar favorable results in the treatment of local infections and also attributed the benefit to the induced leucocytosis. Certain phases of Ferguson's work have been confirmed and amplified by Thomas (3).

It is clear, therefore, that not only the teachings of pathology with reference to the rôle of the white blood cells as phagocytes but also actual clinical results justify the conclusion that artficially induced leucocytosis is of definite value in the treatment of

local inflammatory disturbances. As expuralgin induces leucocytosis, its administration in local inflammatory affections would appear to be indicated for the amelioration of the condition itself as well as the relief of pain.

urine and determinations of acidity and uric acid.

From an examination of Table II, certain facts with reference to the effect of expuralgin on uric acid elimination will become evident. The level of uric acid in the blood was not influenced. While there

Expuralgin administered: 2 gm. daily for ten days.
Franke-Benedict method for uric acid determinations in urine.
Franke-Hitchcock method for uric acid determinations in blood.

EFFECT ON URIC ACID METABOLISM

In order to ascertain whether expuralgin has any effect on the uric acid metabolism, studies were conducted on eight human subjects. Three were normal subjects; four had the rheumatic diathesis, and one had arthritis deformans. All of the subjects were kept on a purin free diet for ten days, during which

was a slight reduction in six of the eight subjects, it was too slight to be of any importance. The findings with regard to the uric acid elimination in the urine were more definite. In all eight subjects, the uric acid elimination was increased by the drug. This increased output was much more marked in the rheumatic cases and those of arthritis deformans than in the normal subjects.

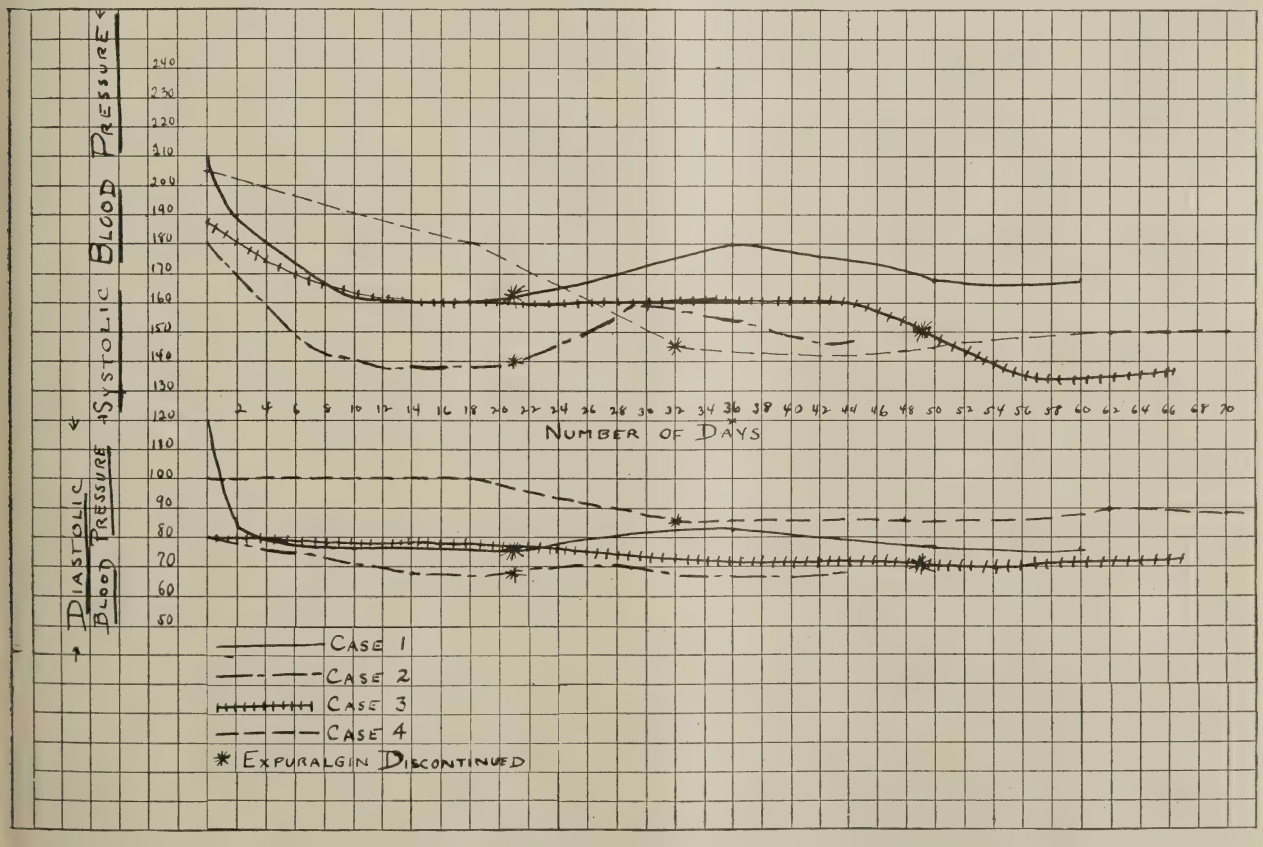

FIG. 1.—Graphic record of four cases of vascular hypertension to show the sustained reduction in systolic and diastolic blood pressure effected by expuralgin medication.

time they received two gm. of expuralgin daily. Uric acid determinations by the Franke-Benedict method were performed before and after the period of medication; also twenty-four hour measurements of the

Usually diuresis did not become apparent until after the second or third day. In general, the effects of expuralgin on diuresis and uric acid elimination in the urine were similar to those observed by Kahn

and Cohn (4) after the administration of allylphenylcinchonin ester (atoquinol). The blood uric acid values were not lowered after the administration of expuralgin as after atoquinol, probably because of the fact that these original values were not so high in my cases as in the series studied by Kahn and Cohn.

Some authors attribute the increased uric acid elimination following the use of atophan and allied drugs to excessive leucocyte destruction. So far as expuralgin is concerned, this hypothesis cannot hold, since the leucocyte count is definitely increased by its administration.

EFFECT ON BLOOD PRESSURE IN HYPERTENSION

The slight fall in blood pressure observed in the eleven normal subjects to whom expuralgin was administered prompted me to investigate the effects of this drug in cases of vascular hypertension. In the four cases studied, the results were striking. In Fig. 1, it will be noted that there was a prompt and prolonged fall in the blood pressure in all four cases after medication with expuralgin. The drug would appear to have a definite vasodilatory action, which persists for some time after its administration has been discontinued. Although the number of cases reported was too few and the period of observation too short to permit of a definite conclusion, the results in the four cases reported were striking and consistent enough to indicate that expuralgin is a valuable remedy for the reduction of high blood pressure.

Patients with hypertension due to arteriosclerosis usually do not respond favorably to expuralgin. Whether the arteriosclerosis is general or localized, the tolerance for the drug is poor. It does not seem to matter whether the localization of the arteriosclerosis is in the brain, heart, kidneys, or elsewhere.

When an arteriosclerotic patient receives a ten grain dose of expuralgin, he begins, within a short period, to suffer from unfavorable symptoms. He complains of slight headache, vertigo, a sensation of warmth throughout the body, and hot flushes. This reaction is so constant that a ten grain dose of expuralgin may be used as a diagnostic test of arteriosclerosis, either general or localized. The normal subject experiences none of these unfavorable effects.

In the cases of hypertension investigated, the effects of expuralgin in reducing high blood pressure other than that due to arteriosclerosis were so favorable that this subject is now being thoroughly investigated. This research will furnish the basis for a further report.

REPORT OF CASES

Thirty-six patients with various painful neuritic, arthritic, and rheumatic afflictions were treated with expuralgin. For convenience of description, these cases have been divided into three groups; namely, thirteen acute cases, ten subacute, and thirteen chronic.

Acute cases.—These cases comprised the following conditions: Three cases of neuritis involving the upper extremities; two cases of lumbago (rheumatic myositis); two cases of facial neuralgia; two cases of sciatica; two cases of sinusitis; one case of myositis of the sternomastoid muscle; and one case of acute rheumatic polytenosynovitis with erythema nodosum.

Medication consisted of ten grains (0.65 gm.) of expuralgin every three hours until acute pain subsided, then eight or ten grains (0.52-0.65 gm.) every four hours until complete and lasting relief was obtained. Liberal amounts of water were taken with the drug. The average amount of the drug taken per patient varied from ten to seventy-five gm. over a period of from three to twenty days.

The results were as follows: There was complete relief of the symptoms with a favorable outcome in nine cases, or sixty-nine per cent.; partial or temporary relief, in three cases, or twenty-three per cent.; and no relief, in one case, or eight per cent. The refractory case was one of sacroiliac disease with sciatica of several years' duration.

Subacute cases.—These cases comprised the following conditions: Four cases of neuritis in various parts of the body; four cases of arthritis involving various joints, and two cases of tenosynovitis (rheumatic).

Medication consisted of ten grains (0.65 gm.) of expuralgin every three or four hours, depending on the severity of the condition; then the dose was reduced to five to eight grains (0.324-0.52 gm.) until the symptoms subsided. The average amount of the drug taken per patient varied from ten to seventy-five gm. over a period of from ten to thirty-five days.

The results were as follows: There was complete relief of the symptoms with a favorable outcome up to the date of this communication (two to three months after the cessation of treatment) in seven cases, or seventy per cent.; temporary relief, lasting only while taking the drug, in three cases, or thirty per cent. All of the patients in the subacute group showed some benefit from the drug.

Chronic cases.—These cases comprised the following conditions: Ten cases of chronic rheumatic diathesis with various rheumatic manifestations lasting from one to six years; two cases of migraine of many years' standing, and one case of arthritis deformans, involving the wrist and fingers of both hands.

Medication consisted of thirty-one grains (two gm.) of expuralgin a day in divided doses. (The dose was different in the two cases of migraine.) When relief was afforded, the dose was diminished in the same manner as in the subacute group, although ten grain (0.65 gm.) doses were required more frequently and over longer periods of time.

The results were as follows: There was complete and permanent relief from all symptoms (four to eight weeks after cessation of treatment) in five of the ten cases of rheumatic diathesis, or fifty per cent. Four of these ten patients, or forty per cent., showed amelioration of the symptoms while taking the drug and for a short period after its discontinuance. In one case, or ten per cent., there was no apparent benefit from the medication. However, in this case there was some question whether the patient took the remedy regularly as directed.

The patient with arthritis deformans was given two gm. of expuralgin daily for a period of seven weeks. She experienced definite relief from her symptoms and showed improved mobility in her fingers.

In the two cases of migraine, the attacks of severe headache were controlled or arrested by expuralgin in doses of ten to twenty grains (0.65-1.3 gm.). In both cases, the intervals between the attacks were lengthened.

The Treatment of Gastric and Duodenal Ulcers*

MAX EINHORN, M.D.
New York

The subject of ulcers of the stomach and duodenum is still surrounded with numerous unsolved problems. The etiology has not been definitely settled and the treatment, medical or surgical, still forms a controversial point of discussion among physicians and surgeons. While the various theories regarding the etiology of peptic ulcers have to a certain extent a secondary influence on their management, the decision whether the treatment should be medical or surgical is of the highest practical importance. It must be answered by the practitioner at once when facing the situation.

It will, therefore, not be taken amiss if I limit my paper to the report of a few new cases of penetrating ulcers and one also of hourglass stomach observed and their treatment. In this connection I shall give the result of a follow up investigation of my old cases of penetrating ulcers described before. It will then be easier to answer the question whether the medical treatment of peptic ulcer is of value.

The cases of penetrating ulcer of the stomach and duodenum recently observed are the following:

Case I.—March 10, 1925 (Lenox Hill Hospital). Nathan H., sixty-two years old, complained for six months of pains in the epigastrium about one half hour to an hour after meals, lasting an hour or so. Light foods caused less distress than coarse substances. The patient ate less and less and lost thirty pounds in weight. He felt weak, could not sleep well, and vomited occasionally. His bowels were sluggish. Lately the patient was more or less bedridden; he took only little of the lightest foods and even then atropine and at times morphine were required to keep his suffering in abeyance.

The physical examination showed slight dilatation of the heart to the right and low sounds. The liver was slightly enlarged. The epigastrium was slightly painful to pressure. The stomach extended to one finger's width below the navel.

The gastric contents showed hydrochloric acid plus; total acidity, 60; no blood. The string test was as follows: blood stain 40-50 cm.; bile stain 60 cm. to the end.

The x ray showed a hazel nut sized niche in the middle third of the lesser curvature, best seen in the oblique position. The diagnosis of penetrating ulcer was made.

Although the possibility of malignancy could not be excluded, it appeared best to give the patient first the benefit of medical treatment. His weak heart seemed to give the patient a poor chance for surgery.

The patient was put upon duodenal feeding. His suffering continued for a few days under this régime requiring codeine to allay the pain. Soon, however, the patient's condition improved. From the fifth day of duodenal alimentation no sedatives were required. The only medication he received consisted of calcined magnesia two gr. and bismuth subcarbonate iss t. i. d. in water, by mouth.

During this treatment the duodenal contents were examined in the fasting state with the following result: dark, yellow, turbid, alkaline, brownish particles containing bunch berry crystals were present; A=5; S=3; T=3.

After two weeks of duodenal alimentation a renewed examination by the röntgen rays showed that the niche had entirely disappeared. The tube was removed and the patient was fed by mouth. A few days later the patient was able to eat ordinary foods without discomfort. He remained well and has gained considerably in weight and strength. One year later he sent a report that he attended to his business right along and felt perfectly well.

Case II.—Joseph K., December, 1925 (Lenox Hill Hospital). This patient was thirty-six years old, single and a painter by occupation.

He complained of pain in the epigastrium for three months; the pain was sharp in character. It was located in the epigastrium and occasionally radiated to the back. The pain came on two hours after meals and was relieved by food. There was no history of previous attacks. The bowels were constipated. There was tenderness in the epigastrium. The string test showed a blood stain nineteen and a half inches from the lips. The Wassermann test was negative.

The stomach contents were: hydrochloric acid=66; acidity=88. The stool was negative for blood. The x ray of the stomach showed a niche in the bulbus (Fig. 1).

*Read before the Harrisburg Academy of Medicine on May 28, 1926.

The patient was treated by duodenal alimentation. He was very much better. After treatment the patient was x rayed again and the niche had disappeared (Fig 2).

Case III.—E. de V., forty-three years of age, (Lenox Hill Hospital). This patient began to suffer three years ago from epigastric distress about one

Fig. 1.—J. K. October 21, 1925. Before treatment. Small niche on the lesser curvature of the duodenum.

hour after meals from time to time. For the last three months the patient's trouble became more aggravated. His appetite was very poor and there were pains in the gastric region pretty soon after meals. Patient lost considerably in weight and strength.

Physical examination revealed tenderness on pressure over the entire epigastrium. The stomach was slightly dilated, extending two fingers' width below the navel. The liver was enlarged. Patient looked emaciated and pale. The urine was free from sugar or albumin. The blood count was as follows: hemoglobin, 85 per cent.; red blood cells, 5,360,000; white blood cells, 13,400; polymorphonuclear, 70 per cent. The gastric contents showed hydrochloric acid plus; acidity=20. The string test revealed a blood stain 18-19 inches from the lips; the bile stain was 23 inches from the lips to the end of the string. The duodenal contents were dark red, and very turbid (blood was present); alkalinity was 30; amylopsin, 10; steapsin, 3; trypsin, 1; red blood cells, mucus and cholesterin crystals were present.

The x ray examination of the stomach revealed a niche of large size in the middle third of the lesser curvature. The diagnosis was penetrating ulcer of the stomach.

The patient was put on duodenal alimentation. The pain first persisted and for a few days hot applications and opiates had to be employed. Soon, however, the patient was more comfortable and there was no need of any sedative remedies.

Two weeks after the treatment the size of the ulcer not being diminished the duodenal alimentation was carried on for another week. A new x ray showed considerable reduction in the size of the niche. The tube was then removed and the patient fed by mouth (Figs. 3, 4, 5).

The patient had to leave for his native country (Spain) and was advised to have x ray pictures taken from time to time. In the event that the niche did not disappear he was advised to have an operation. The patient is now (one year) attending to his business and comfortable without any operation, although using antacid powders from time to time.

Case IV.—B. S., forty-five years old; April 1, 1926 (Lexington Hospital). The patient had been complaining of dull pain in the epigastrium for the past two months. He had a similar attack one year ago, which lasted about three weeks. The pain came on two hours after eating, dull in character, did not radiate but was localized in the epigastrium. Food and bicarbonate of soda relieved the pain. Occasionally it awakened him at night; no vomiting; no loss of weight. Patient was constipated and at times troubled with gas and sour eructations.

The gastric contents were hydrochloric acid plus; acidity, 90; blood plus. The string test showed a blood stain 56-58 cm. from the lips; bile stain 60 cm. to the end. The x ray revealed a niche on the inner border of the duodenum. The urine showed a faint trace of albumin. The physical examination showed tenderness in the epigastrium and a slightly swollen liver. The patient entered the Lexington Hospital on April 1, 1926, and the feedings were started on April 4, 1926. The tube was removed on April 20, 1926. The patient felt very comfortable. The niche had disappeared after the patient had been treated for two weeks (Figs. 6 and 7).

Case V.—W. D., April 5, 1926, fifty-nine years old (Lexington Hospital). The patient had typhoid fever seven years ago. This patient had pain in the epigastrium for the past month. He had a similar trouble about four years ago. The pain was located in the stomach, just above the umbilicus, came on one and one half hours after eating, was relieved by food and radiated straight through to the back. Two attacks of pain were so severe that morphine was resorted to. The patient was slightly constipated. He vomited a few times.

The gastric contents were hydrochloric acid, plus; acidity, 35; blood plus. The string test showed a

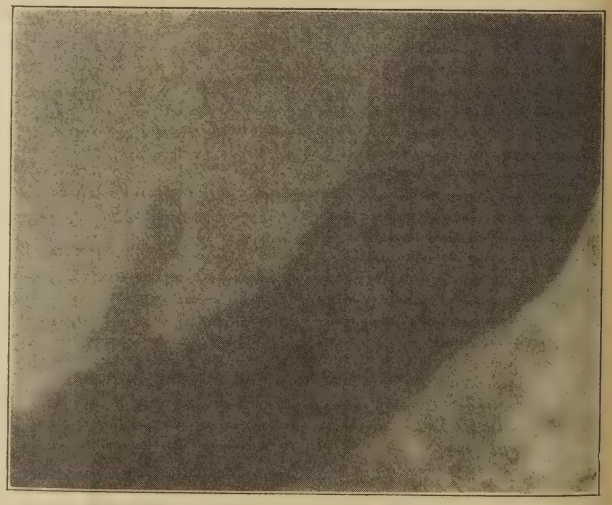

Fig. 2.—Same patient as in Fig. 1. November 14, 1925. After treatment. The niche had disappeared.

blood stain 50-53 cm. from the lips; bile stain 55 cm. to the end. The x ray showed a large penetrating ulcer on the lesser curvature of the stomach. Wassermann was negative. The physical examination revealed tenderness in the epigastrium.

The patient was admitted to the Lexington Hos-

pital on April 2, 1926. The duodenal feedings were started on April 5, 1926. The tube was left in the duodenum five weeks. It was removed on May 7, 1926.

During the treatment the niche had gradually decreased in size, so that at present it is one tenth of its original size (Figs. 8, 9, 10, 11, 12). Patient is feeling very well and is eating a liberal diet.

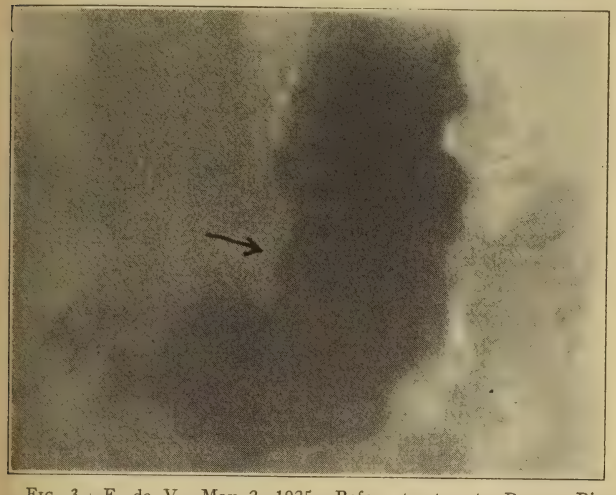

FIG. 3.—E. de V. May 2, 1925. Before treatment. Prone. Big niche in the middle of lesser curvature of stomach.

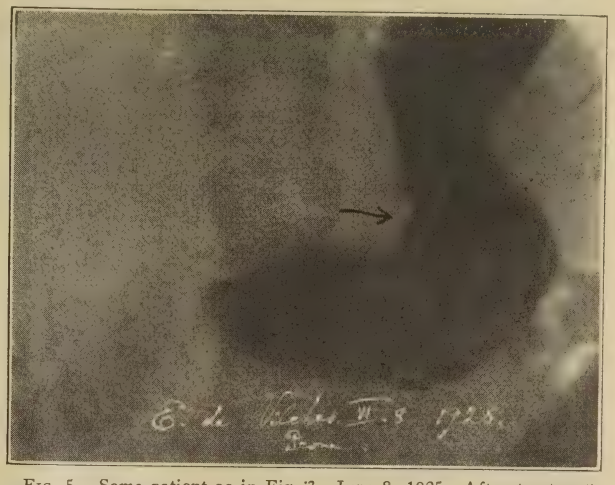

FIG. 5.—Same patient as in Fig. 3. June 8, 1925. After treatment. Prone. The niche is hardly one fifth of its former size.

CASE VI.—Mrs. Anna F., sixty-one years old; March 1, 1926 (Lexington Hospital). This patient had been complaining of pain in the stomach for the past two weeks. Patient had been operated upon six years ago for a gastric ulcer, a resection having been performed. She was well until eight months ago, when she began to have pain in the stomach about one hour after eating. The pain was severe and the patient was unable to eat at the time she had the pain. She was treated by duodenal feeding and felt well until two weeks ago. Since that time the patient has had severe pain in the epigastrium one hour after meals. The pain was rather severe and was not relieved by food. Bicarbonate of soda gave her some relief, but at times even this failed to relieve the pain. Patient also complained of heartburn and belching of gas and constipation. She vomited occasionally. The patient had lost ten pounds in weight in two weeks.

The gastric contents were hydrochloric acid plus; acidity, 70; blood negative. The string test showed a blood stain 40-42 cm. from the lips and bile stain 50 cm. to the end of the string.

The physical examination revealed tenderness in the epigastrium and the entire left lower quadrant. The tongue had several large patches on it, which were tender and free from the coating, covering the remainder of the tongue. The liver was slightly swollen. The patient looked as though she had been suffering.

The x ray examination showed a typical hour glass stomach. After atropine the same picture was obtained by the x ray (Fig. 13).

The patient was admitted to the Lexington Hospital on March 1, 1926, and duodenal feedings started on March 3, 1926. The tube was removed on March 14, 1926. After treatment the hour glass contraction disappeared (Fig. 14). The patient is feeling well and takes a liberal diet.

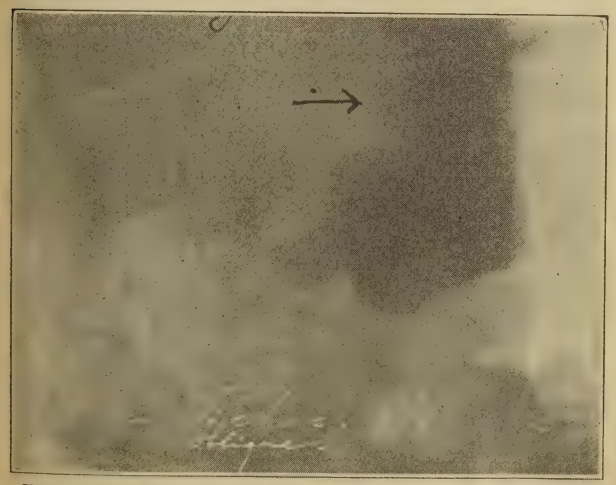

FIG. 4.—Same patient as in Fig. 3. May 8, 1925. Oblique. Large niche in the middle of lesser curvature of stomach.

FIG. 6.—A. Salzman. March 15, 1926. Before treatment. Small niche on the lesser curvature of the duodenum.

Two cases, one of gastric ulcer (E. K.) and one of duodenal ulcer (M. D.) recently occurred in patients who had been treated by me before. Following is a brief sketch of them:

Case VII.—E. K. (first admission), aged forty-two, married, chauffeur by occupation, was admitted to the Lenox Hill Hospital, November 17, 1920.

The patient complained of epigastric pain coming on about one and one half hours after eating, relieved

Fig. 7.—Same patient as in Fig. 6. May 14, 1926. After treatment. The niche has disappeared.

by food or belching. This pain had been present on and off for two years, although the patient complained of pyrosis for ten years. The patient vomited one quart of blood two weeks ago. The bowels were constipated.

The gastrointestinal series of x rays were negative. The string test was positive, the blood stain being present 21½ inches from the lips.

The patient was placed upon duodenal feedings and he was discharged from the hospital December 13, 1920.

Second admission—December 8, 1921.

The patient was relieved from symptoms until three weeks ago, when he had a similar recurrence. The x rays showed an infiltration and distinct protuberance along the lesser curvature. The patient was treated and the x rays showed that the ulcer had disappeared. He was discharged from the hospital January 4, 1922. The patient had gained forty pounds and was perfectly well for over four years.

Third admission—January 8, 1926.

The patient was free from symptoms until eight weeks ago, when he ate a cheese sandwich and was seized with cramplike pains in the abdomen. Since then he had suffered from pain in the epigastrium after eating.

The gastric contents were hydrochloric acid, 60; acidity, 72. The string test was negative. The stool was negative for blood and the Wassermann was negative. The x ray showed an ulcer of the posterior surface with incisure. After two weeks of duodenal alimentation the patient feels well. The incisure is not visible on the plates but fluoroscopic examination still shows it at times.

Case VIII.—M. D., admitted to the Lenox Hill Hospital on December 29, 1923. This patient was thirty-four years old and a waiter by occupation (first admission).

The history was as follows: Patient had cramplike pains in the epigastrium.

The patient had a bladder operation in 1921; appendectomy in 1919. Five years ago he had a similar attack of stomach trouble for which he sought treatment now. For the past three weeks the patient had been having cramplike pains in the epigastrium immediately after meals. He vomited occasionally.

The x ray showed a protruding niche on the lesser curvature. The patient was placed upon duodenal feeding. After treatment he was x rayed again and the niche had disappeared. The patient was discharged on January 31, 1924.

Second admission—January 9, 1926.

The patient was free from symptoms until four weeks ago. Since then he has been complaining of severe cramplike pains in the abdomen. They radiate to the back and are somewhat relieved by eating; no vomiting; no tarry stools; no loss in weight. The patient had been eating everything.

The gastric contents were hydrochloric acid, 38; acidity, 64. Wassermann, A=0; C=2 plus. The x ray showed a deformity of the cap which disappeared after duodenal alimentation.

The result of treatment in the new cases just described was very good. The niches have disappeared in all, excepting in two, E. V. and D., in whom about one tenth of the original niche is still visible. The probability is that in from two to four weeks even this remnant of the pouch will entirely vanish. In Mrs. F. the hour glass stomach has disappeared.

In order to have an idea of the permanency of the

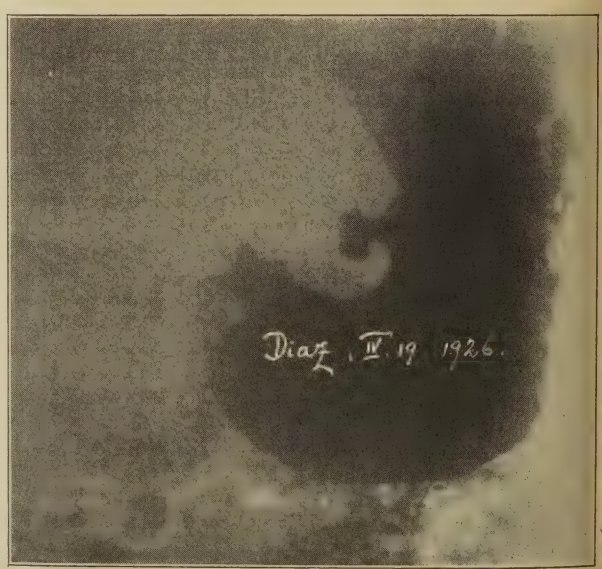

Fig. 8.—W. D. April 19, 1926. Before treatment. Large niche, mushroom form, on the middle of lesser curvature.

results of treatment I have tabulated my cases (1921-1926) of ulcers of the stomach and duodenum, in which visible niches or deformities were seen by x rays before treatment and had disappeared after treatment, with a follow up to date. Two cases of big penetrating ulcer of the lesser curvature of the

stomach with probable malignancy and one case of duodenal ulcer with Hodgkin's disease are not included in this group (D, K. R., and S. H.). But even in the malignant type of ulcer there may be at first a retrocession of the process for quite a while.

FIG. 9.—Same patient as in Fig. 8. April 26, 1926. During treatment. Niche somewhat smaller. Capsule end of tube visible beneath the stomach.

In looking over the table containing the cases of penetrating and callous ulcers of the stomach and duodenum treated by me since 1921 with a follow up to date, the following can be said:

Immediate good results were noted in all of the thirty-four cases. The further progress was good in thirty cases, and merely bearable in two (W. and R.). In two operations became necessary after the cure of the gastric ulcer. There were adhesions over the duodenum and gallbladder in one. He was operated upon and is alive and in good health up to date. In the other after a recurrence and cure of the ulcer, an operation for a chronic cholecystitis was performed. The patient died on account of a weak heart and bad liver. We could not obtain any information about two patients (S. K. and J. L.). Another patient (Karl B.) died one year later from pneumonia after having been in perfect health. All the others are well excepting two (E. K. and M. D.) who had recurrences of ulcers but not in the same spot and were treated with duodenal alimentation with good result. They are both described in this paper (Cases VII and VIII).

Cases L. K., A. R., J. W., and W. D. (Nos. 2, 3. 22, and 32, of the accompanying table) are of great interest in showing the gradual steps of the healing process extended over a period of six weeks to three months, the niche becoming gradually smaller until it entirely disappears.

With regard to recurrence of peptic ulcer we can put it at ten to twenty per cent., this variation depending upon the length of time and mode of living. If we consider that all these cases of callous and penetrating ulcer have been considered up to a few years ago by physicians and surgeons alike as belonging to the domain of surgery, we must say that the results obtained are more than satisfactory. The question, therefore, whether peptic ulcers (in the general run, which are certainly not as severe as those here described) should be treated medically or surgically must be answered "medically," with emphasis.

Having decided the main point at issue it behooves us to discuss in a few words the treatment of peptic ulcer, considering first its medical management and second the selection of those cases in which surgery is indicated.

The principle of rest plays the first and greatest part in the healing of peptic ulcers. The second point of importance is adequate nutrition, especially if a dietary régime should be applied for a longer period of time.

Erosions and small ulcers heal frequently without any medical aid. If the affection reaches a certain degree and the process becomes more extensive, then the healing does not take place by itself. The patient becomes aware of disturbances in the act of digestion and he is forced to seek medical aid.

The extent of suffering and the ability to undergo treatment play a part in the selection of a suitable plan of treatment. Thus in severe cases (hemorrhages, vomiting, pains in the upper abdomen) rest in bed, abstinence from food by mouth, rectal feeding and rectal instillation of fluids by the Murphy drip, used to be and still is, to a certain extent, the general mode of procedure. In the same instances duodenal

FIG. 10.—Same patient as in Fig. 8. May 3, 1926. Niche about one eighth its original size, still mushroom form.

alimentation can be instituted with greater comfort and advantage to the patients. This mode of procedure combines the principle of rest and adequate nutrition and has the advantage that it can be applied for a long time. In patients who are willing to sub-

TABLE OF CASES OF PEPTIC ULCERS ACCOMPANIED BY DEFORMITIES VISIBLE BY X RAYS TREATED MEDICALLY AND FOLLOWED UP TO DATE. (1921-1926.)

	1921		1926	Remarks
1.	E. K.	Stomach	Gained in weight, feels all right.	Felt all right till 1926, then came back with a new ulcer of another part of the stomach. Treated again and the ulcer disappeared.
2.	L. K.	Stomach	All right ever since treatment, gained eighteen pounds	
3.	A. R.	Stomach	All right, gained forty pounds.	
4.	A. B.	Duoden.	All right.	
5.	J. L.	Duoden.	Not heard from.	
6.	A. G.	Duoden.	All right.	
	1922			
7.	S. D.	Stomach	Attends to his business feeling all right.	Two years after treatment slight attack of cholecystitis. Stomach examined by x ray and no ulcer found.
8.	J. E. Mc.	Stomach	All right.	Had a gastric ulcer; operated one year later for adhesions over the duodenum; gastroenterostomy having been done with good results.
9.	H. A.	Pylorus	Gained in weight, feels all right.	
10.	F. D.	Stomach	Gained in weight, feels all right.	Before treatment defect in the pyloric portion of the stomach; after treatment the defect almost disappeared.
11.	T. F.	Stomach	Gained in weight, feels all right.	Before treatment the pylorus was lengthened and rigid, after treatment deformity less marked.
12.	Miss I. W.	Stomach	Alive and complaining. (Gained fifteen pounds.)	Before treatment defect in the prepyloric portion of the stomach and sacculation in the second part of the duodenum; after treatment defect and sacculation disappeared.
13.	Mrs. B. Mc.	Duoden.	All right.	
14.	Mrs. C. H. R.	Duoden.	Still complaining. (Gained thirty pounds.)	
15.	J. P. B.	Duoden.	All right.	
16.	K. B.	Duoden.		Attended to his business as a chauffeur for one year, then died of pneumonia.
17.	M. S.	Duoden.	All right.	
18.	T. K.	Duoden.	Not heard from.	
	1922			
19.	J. B.	Duoden.	All right.	
20.	F. M.	Duoden.		Had recurrence one year later and improved under treatment; died after operation for gall bladder.
21.	H. M.	Duoden.	All right with exception of neuritis.	
	1923			
22.	J. W.	Stomach	Gained 40 pounds in weight, is attending to his business, perfectly well.	
23.	J. H. O.	Stomach	Gained thirty pounds, feels good and attends to his business.	Christmas 1925 patient indulged too much in alcohol and suffered from digestive disturbances for a short time. Re-examination with x ray showed that the niche was missing.
24.	D.	Stomach	Gained in weight, feels good.	Had a relapse December, 1925, but the ulcer was in another part of the stomach; duodenal alimentation removed the symptoms.
25.	Mrs. F. S.	Stomach	All right.	
	1924			
26.	W. L.	Stomach	Gained in weight, feels all right.	Six months after the cure of the ulcer, was operated for appendicitis.
27.	J. R.	Stomach	Gained thirty-five pounds in weight, feels all right.	Good sized niche.
28.	C. E.	Stomach	Gained in weight, feels all right.	
	1925			
29.	E. de V.	Stomach	Gained in weight, feels all right, but takes antacid medication.	
30.	N. H.	Stomach	Gained in weight, feels all right.	
31.	J. K.	Duoden.	Feels all right.	
	1926			
32.	D.	Stomach	Feeling good, niche smaller (one-tenth its original size).	
33.	Mrs. F.	Hourglass Stomach	Feels all right.	
34.	S.	Duoden.	All right.	

Cases 1, 2, 3, 4, 5, 6, 7, 8, 9, 14 were described in the N. Y. MEDICAL JOURNAL December 6, 1922.

Cases 10, 11, 12, 15, 16, 17, 18, 19, 20, 21, 22, 23, 25 were described in the N. Y. MEDICAL JOURNAL November, 1923.

Cases 26, 27, 28 were described in *Annals of Clinical Medicine*, Vol. IV No. 5, November, 1925.

Fig. 11.—Same patient as in Fig. 8. May 14, 1926. After treatment. Small niche about one tenth original size, now a rather small pyramid shape.

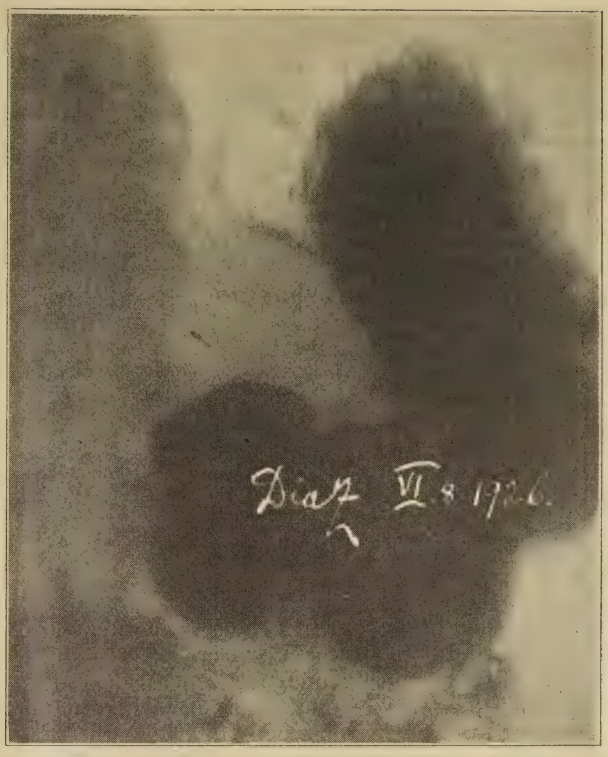

Fig. 12.—Same patient as in Fig. 8. June 8, 1926. Niche has diminished in height but seems a trace wider at its base.

mit to duodenal alimentation, this mode of procedure should be applied in all forms of peptic ulcer (mild and severe).

All other phases of treatment carry out the principle of rest only partially. To these belong Cruveilhier's milk régime, Leube-Ziemssen's rest régime and diet (milk and gruels), Lenhartz's diet, milk, eggs and meat with restriction of fluids), Sippy's diet (feeding every hour and the addition of alkalies), Coleman's diet (white of eggs, olive oil or butter by the stomach and glucose instillation by rectum).

Most of the patients are kept in bed. In mild cases, however, an ambulatory régime is also at times permissible. Here a liberal diet, frequent meals and

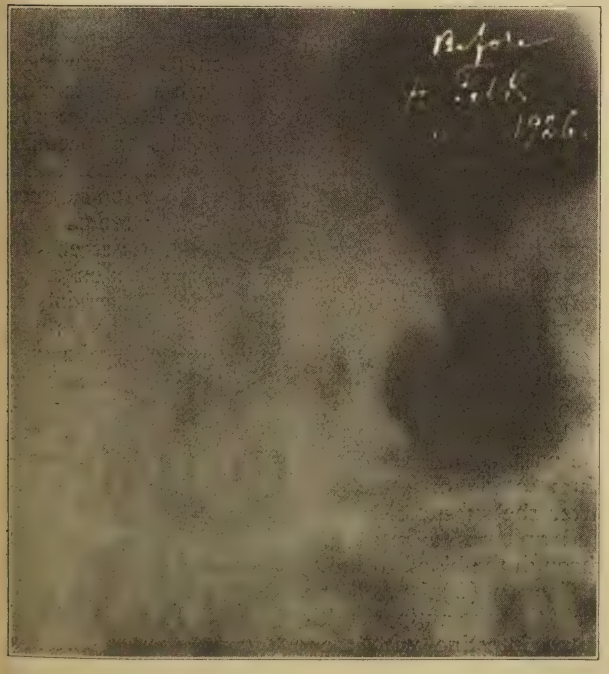

Fig. 13.—Mrs. A. F. March, 1926. Before treatment. Hourglass stomach.

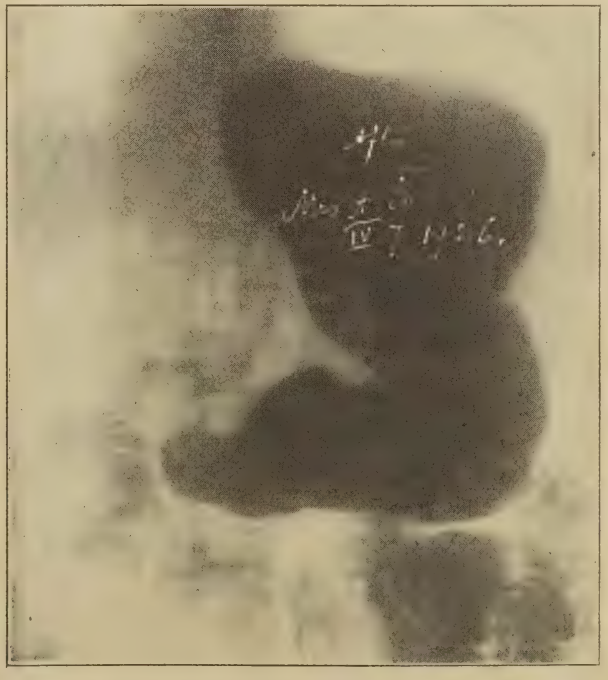

Fig. 14.—Same patient as in Fig. 13. April 7, 1926. After treatment. The stomach has assumed an almost normal configuration.

avoidance of highly seasoned substances are the main features of the treatment.

In the way of medication bismuth, alkalies, olive oil and antispasmodics (atropine, papaverin), nerve sedatives, and mild aperients form the main remedies generally employed.

The indications for surgery (in peptic ulcers) are:

1. Perforation of the ulcer.
2. Ulcers leading to obstruction of the pylorus.
3. Ulcers of stomach with malignancy suspected.
4. Callous ulcers (niches) not yielding to rigorous treatment.
5. Recurrence of massive hemorrhages from the stomach or duodenum endangering life of patient.
6. Small gastric hemorrhages which go on uninterruptedly, resist all kinds of treatment, and endanger the life of the patient.
7. Gastric distress resisting all modes of repeated rational treatment, extending over a long period of time, and making life unbearable.

Before concluding I would like to express my obligations to William H. Stewart and H. A. Rafsky for the x rays taken from the last series of cases.

20 East Sixty-third Street.

Rectal Feeding

CHARLES J. DRUECK, M.D.,

Chicago

In presenting this subject I wish to state that I am not so enthusiastic as to suggest this method of alimentation as a substitute for conveying the nutriments by the normal avenue, but rather as a resource in the treatment of certain conditions where it may be desirable, or even imperative, to relieve the stomach of all food for a time, and thus temporarily sustain the patient by mechanically introducing food substances into the rectum and colon by way of the anus.

It has long been recognized that all mucous membranes will absorb certain substances and pass them into the lymphatics, but only recently has this knowledge been applied to rectal feeding. Kelsey cites numerous authors who speak of the relative absorbing power of the rectal and gastric mucous membranes, and we find a considerable proportion of these writers conclude with an evasive statement to the effect that it has not as yet been definitely established that sufficient nourishment may be absorbed by the mucosa of the rectum and sigmoid colon to sustain life. Bauer, for instance, asserts that "not more than one fourth of the necessary nutriment, even under the best conditions, can be absorbed from the rectum." Such statements, in the light of our present knowledge, must be modified, however, because experience has shown that many patients not only live but some even gain slightly in weight when the injections are carefully given according to the directions that will be described further on.

Thompson (1) supported a patient seven weeks and Flint (2) tells of a patient who was nourished for fifteen months by rectal feeding alone, and who had been maintained chiefly by this method for five years. These are, of course, extreme cases, but it is safe to say that the average patient may be maintained for three to four weeks exclusively by colonic feeding and this is sufficient time to produce good results in most instances. Friedenwald and Rühräh, in their work, state that a person may be thus sustained for from four to seven weeks.

It is true, food given by the rectum cannot yield anywhere nearly as much nourishment as when taken into a healthy stomach by way of the mouth, because, with but rare exceptions, we can utilize only the large bowel; and yet, I believe that colonic feedings pass through into the small intestine much more frequently than we are prepared to admit. As a matter of fact, in colonic feeding, we certainly supply to the system all of the necessary fluids and inorganic salts, and at least part, and possibly all, of the amount of food required to sustain the individual while at rest.

Feeding by way of the rectum has been objected to mainly on theoretical grounds, with reference to the physiology. As to this I might reply that, so far as my experience shows, the method of administration very often is at fault.

The rectum proper (that is, the last six inches of the gut) has very limited absorbing power, but Landois has shown that the colon possesses a very marked assimilative power, although the digestive ferments of this part are feeble. Consequently, properly prepared foods are readily taken up from the colon, thus insuring a considerable nourishment to the system.

Recognizing the fact that patients are nourished by foods administered per rectum, while maintaining that the secretions of the rectum have little digestive power, certain authors have advanced most peculiar theories as to how assimilation is accomplished.

Flint, for example, says (3): "When food comes in contact with the rectum, while the stomach is empty, the gastric and intestinal juices descend to the rectum." Dr. Batty, from experiments on cadavers, concludes that the injected food ascends the whole digestive tract, instead of remaining in the rectum or colon. He thus accounts for the phenomenon of patients being able to taste substances such as quinine or castor oil when administered rectally. C. W. Brown, of Washington (4), cites a case where the patient was able to recognize the taste of potassium iodide or of ergot fifteen to thirty minutes after the substance was introduced into the rectum, and assumes a rapid absorption and transmission through the blood to the taste bulbs and the saliva.

Cannon (5) has observed by radiographs on animals that the antiperistaltic waves filled many coils of small intestine with the enema mixture. After a short time the segmenting movements were seen in the loops, separating the food into small masses and

over and over again dividing and redividing them.

In practice, however, the retroperistalic action, whereby the enema is carried through Bauhin's valve into the small intestine, is the exception and most of the nutrient probably is absorbed directly from the colon. Voit and Bauer were the first to find that sodium chloride added to meat juice and peptones greatly adds to their absorbability when given in an enema, but the salt stimulates reverse peristalsis to such an extent that many writers (Grutzner and later Swieznski) have demonstrated in the stomach substances that have been administered per rectum.

PRINCIPLES OF RECTAL FEEDING

In rectal feeding, the minutest details are important; and, indeed, the enemata should always be administered by the physician himself, instead of intrusting the task to a nurse, inasmuch as the patient's life generally depends upon his ability to endure continuation of the treatment. If the rectum becomes irritated, it usually means suspension of this mode of feeding; and yet only rarely can the feedings be withheld long enough to permit the local trouble to subside. Occasionally it happens that a patient will object to rectal feeding, for esthetic reasons; and then the physician must use tact and persuasion.

Before going into the details of rectal feeding, I desire to impress the following facts upon the reader as being very vital to the success of the treatment: 1. The rectum must be free from feces and mucus before giving the enema. 2. Any irritability of the rectum is to be relieved as quickly as possible. 3. The quantity and quality of food introduced must be regulated carefully, to avoid peristalsis, and to allow complete absorption of one portion before another is injected.

INDICATIONS FOR RECTAL FEEDING

Feeding by way of the rectum is indicated under the following circumstances:

1. In temporary obstruction to the entrance of food into the alimentary canal, as by new growths, foreign bodies, inflammatory swellings of the mouth, pharynx or esophagus resulting from disease, corrosive poisons such as carbolic acid or ammonia or from hot fluids.
2. Inability to swallow food, as during coma, delirium or in postdiphtheritic paralysis; also during acute insanity when food is refused by mouth.
3. In gastric disturbances, such as acute gastritis, ulcer or cancer (when it is desired to rest the stomach), reflex vomiting of pregnancy, or sea voyages.
4. In stricture of the lower digestive tract anywhere above the colon.
5. In weak digestion and increasing emaciation.

MODE OF ADMINISTERING THE ENEMA

The utmost care is necessary in the manipulations, because irritation and injury to the rectum are inevitable if careless, rough or unskilled attempts are made. I mention the ordinary syringe with the short nozzle only to condemn it. For children, a No. 6 "velvet eyed" flexible catheter may be chosen, but for adults a 14 catheter should be employed. The rectal tube should be sufficiently rigid to free itself and not bend or double if it catches in a fold of mucous membrane, and yet, must not be so stiff as to cause pain or damage when introduced. Olive oil, salad oil, melted butter or vaseline may be applied for lubricating; but never glycerin, since this tends to excite peristalsis.

Just how far the rectal tube can be passed into the colon is a mooted question. Certain authorities say they are able to reach the transverse or even descending colon, while others (Nothnagel, Naunyn Boas) maintain that the tube invariably coils upon itself in the ampulla, or dilated portion of the rectum. Rosenberg and Lilienthal found that by using the sigmoidoscope they could pass a soft tube as far as the middle of the sigmoid flexure, but no further; the greatest distance being thirty centimetres, or twelve inches. Soper has carried out a series of experiments, with the patient on the side and in the knee-chest position, and found that the tube invariably coiled up in the ampulla. In the *Journal of the American Medical Association* for August 7, 1909, he shows radiographic pictures of the position of the tube. He shows positively that the rectal tube seldom passes more than six or eight inches into the rectum without kinking and that to introduce it farther causes, 1, kinking of the tube and obstructions to the flow of liquid into the bowel, and 2, such distention of the bowel as to stimulate evacuations. This latter fact undoubtedly is one of the causes of failure of retention of nutrient enemata when given "high."

In adults, then, I introduce the tube a distance of six or eight inches. This prevents the ejection of the fluid and brings it in contact with a large amount of mucous membrane. There is also an anatomical reason for passing the fluid high. The blood returned from the colon, sigmoid flexure, and superior hemorrhoidal veins enters the vena cava so that substances absorbed by these latter veins do not go through the liver, while substances absorbed higher up pass through the vena porta to the liver and are there further elaborated.

A fountain syringe or an ordinary stomach tube and funnel may be attached to the rectal tube. The apparatus must be tried before putting it to use, in order to see that all is in working order. It is well to heat the appliances to about 100° F., so as to prevent chilling the nutrient to be introduced, for fluids if too hot or too cold are promptly expelled, an enema at 90° to 95° being retained best.

When everything is ready the tube is filled with the fluid before introducing, to insure the exclusion of air, because air is very likely to stimulate peristalsis and, hence, evacuation. The injection must be given slowly, taking ten or fifteen minutes, because rapid infusion also stimulates unwelcome peristalsis.

One of the first essentials for absorption by the colon is cleanliness within. It is evident that, if the colon or sigmoid flexure is filled with feces or the sides are covered with mucus, it is impossible for osmosis to occur. Consequently before any nutriment is introduced, the colon must be thoroughly emptied and cleansed.

One hour before the time of giving the morning feeding the colon should be flushed with a high injection of one quart of normal salt solution. A return flow catheter must be provided, that the water may find easy exit and thus avoid inciting peristalsis. In many instances, one such cleansing each day will be sufficient; but if much mucus is present it is well to precede each feeding with the cleansing clyster,

and here the salt should be substituted by two teaspoonfuls of sodium bicarbonate. When the rectum is tender or inflamed, a saturated solution of boric acid is borne best. This procedure washes out any undigested food or waste matter, cleanses the mucous membrane, stimulates the local circulation, and thus provides better absorption.

The proper temperature of the flushing solution is a matter of some difference of opinion. Tuttle recommends cold water, because he finds that this acts more promptly and, he thinks, leaves the bowel more tolerant to the succeeding nutrient enema. My own preference, however, is for the solutions at nearly body heat, as they cause less reaction, or, in other words, congestion of the colonic mucosa. The nutrient enema being kept in contact with the tissues for a considerable time, it necessarily must induce some reaction and, if by any kind of treatment we overstimulate and thus irritate the colon, it promptly expels the entire contents; and this may determine our case unfavorably. A very important point is, to flush out the bowel quite a while before giving the nutrient (in my practice I make this about one hour) and then allow the patient absolute rest in bed.

The tube is introduced with a twisting or boring motion, to avoid its becoming caught in the folds of the mucosa. If it meets resistance a little of the fluid is admitted and thereby the gut dilated or ballooned. After the tube has passed the sphincters (about four inches) procedure is suspended for a few minutes, until the temporary excitation has subsided; during this period of rest any colon gas present is frequently expelled. The tube then is pushed as high as desired, to bring the fluid into contact with a large amount of mucous membrane and to lessen the tendency toward ejection.

When the tube is nearly emptied and before any air has a chance to rush in after the injection, it is firmly compressed and slowly but steadily withdrawn. To aid retention, a soft, folded towel should be firmly pressed against the anus for twenty or thirty minutes. This reduces the temporary excitement and the tendency to evacuation. The patient should remain quiet for at least an hour and be instructed to do his best to retain the fluid; cheerful conversation by the doctor or attendant diverts the patient's mind and is of much assistance where there is danger of its not being retained.

A correct position of the patient also assists, the left lateral prone, with the hips raised (on a pillow) usually being sufficient; although, if the patient is nervous or hysterical, it is well to adopt the knee-chest posture. In gynecological or obstetrical cases where enemata are given, it must be remembered that tight vaginal tamponing interferes with absorption from the rectum.

The number of injections a day depends upon the relative irritability of the rectum, and at the beginning they should be one in six or eight hours. If after two days the rectum is in good condition and it is necessary to give small enemata frequently, they may be repeated every four hours. However, frequent clysters usually irritate the rectum and have to be suspended soon.

CARE OF THE RECTUM

The exact condition of the rectum might be determined and explicit instructions given to the nurse when it is desired to continue nutrient enemata. Failure often results from leaving this matter to persons ignorant of the anatomy and the conditions to be observed; when, if the attendant were intelligent and skilled in these details all troubles would be overcome. It is the duty of the physician to do the work himself whenever possible.

In the beginning the clysters may be rejected, but when properly prepared and administered the rectum quite often soon acquires a tolerance, so that the nutrient enemata may be administered in sufficient numbers and volume to support the patient for weeks.

Proctitis is always likely to arise, and it is only occasionally that irritation and diarrhea does not occur within two or three weeks. When this does happen, the enemata must be stopped temporarily to be resumed after the bowel improves. All local troubles, such as ulceration, fissure, fistula, and hemorrhoids are drawbacks. The presence of hemorrhoids is one of the most unfavorable handicaps to the treatment, because they are so easily irritated and inflamed and they then set up a spasmodic contraction of the sphincter. When hemorrhoids exist, great care must be exercised to avoid irritating them by rough usage of the catheter; under these circumstances I always use a soft flexible catheter. If the hemorrhoids are at the orifice, I paint them with a two per cent. solution of cocaine before introducing the fluid, applying immediately afterward a mild astringent and sedative ointment.

(To be continued.)

The Rôle of Infections in Proctology*

FRANK C. YEOMANS, M.D., F.A.C.S.
New York, N. Y.

If we exclude congenital anomalies, trauma, prolapsus and certain neoplasms, infection is responsible for practically all of the remaining pathology of the terminal bowel.

In general the infecting agent is endogenous or exogenous and either simple or specific. Therefore, to gain a clue to the nature of the infection a complete history is requisite, including not only the present illness but residence in the tropics, mouth, throat, and chest conditions, venereal infections, operations, habits of eating and drinking, and exposure. Broadly speaking, we may separate infections into two classes; those which limit their activity chiefly to the bowel wall proper and those which extend beyond it. In-

*Read at the Twenty-seventh annual meeting of the American Proctologic Society, held at Indianapolis, Ind., April 16-17, 1926.

cluded in the bowel wall infections are the various forms of colitis, ranging from the socalled infected colon to chronic ulcerative colitis, which may be the terminal stage of a specific infection, the lesions of which have become secondarily infected by the ordinary intestinal flora. The usual specific infections are bacillary, amebic, gonorrheal, syphilitic or tuberculous. If seen at certain stages in their development, specific infections present lesions diagnostic to direct inspection through the proctoscope or the etiological organism can be recovered and recognized microscopically. This is particularly true of amebiasis, the early, discreet, pearl grey lesions of which are characteristic and the causal amebæ can be demonstrated readily on the warm stage in fresh scrapings from the ulcers. In this latitude amebic infection is of relatively mild intensity but persistent and usually confined to the colon, and its most common complication—abscess of the liver—seldom occurs, three instances being found in about 150 personal cases. In the tropics, on the contrary, the onset is often violent and the course rapidly fulminating with gangrene of the colon and fatal termination.

BACILLARY DYSENTERY

Bacillary dysentery is characterized by considerable elevation of temperature at first and frequent stools which contain the specific bacilli at the onset but they soon disappear under maintained high temperature and the ordinary intestinal flora may secondarily infect the lesions initiated by the bacillus dysenteriæ.

TUBERCULOSIS

Tuberculosis finds its early and chief seat in the cecum and, in the adult, is practically always secondary to pulmonary involvement. Given a history of lung tuberculosis, diarrhea or irregular bowel actions, the fluoroscope may show irritability of the cecum by its rapid emptying in early involvement or, later, delay when the bowel wall is thickened by the inflammatory process. The tubercle bacilli very seldom can be found in the stools. Tuberculous ulcers occur in the rectum and may result in a stenosis or a hyperplasia may develop in this situation—a tuberculoma—which in many features resembles a carcinoma, the true nature of which can be determined only histologically. Tuberculous extension in the perirectal tissues manifests itself as a "cold abscess" the opening of which forms a tuberculous fistula.

SYPHILIS

The primary extragenital chancre is occasionally seen at the anal verge. Secondary lesions of the rectal mucosa have been observed but the tertiary manifestations of syphilis are of chief clinical interest. They occur at first as ulcers of the mucosa with circular infiltration of the bowel wall, the terminal stage of which is stricture, most frequently involving the rectum but occasionally other segments of the colon. One case of gumma in the ischiorectal fossa came under my care.

GONORRHEAL INFECTION

This is usually limited to the rectum unless spread to higher levels by too vigorous irrigations. The history of exposure, an atonic anal canal and creamy pus containing gonococci establish the diagnosis. Suitable treatment promptly relieves the acute symptoms but a protracted catarrhal proctitis usually follows.

ULCERATIVE COLITIS

Chronic ulcerative colitis may be a sequel to amebic or bacillary dysentery, as already noted, but more often is apparently due to some change in the usual intestinal bacteria, rendering them pathogenic, or the normal resistance of the host has been weakened by countless causes. The colon bacillus in its many strains is probably the chief active factor though cultures sometimes show a predominating streptococcus or other organism. Bargen (1) has made a praiseworthy experimental and clinical effort to discover a specific organism. He has described a gram positive, lancet shaped diplococcus having a tendency to form capsules and always appearing in groups of two or four, which he isolated from forty-five to sixty patients having chronic ulcerative colitis. The part played by disturbances of metabolism, avitaminosis, etc., require further study. Whatever the etiology, the final picture is much the same. The early lesions may be mostly in the rectum and the sigmoid but the infection tends to spread upward and may involve the whole colon. Absence of haustrations on x ray plates after a barium clysma indicates fairly well the limits of extension.

The glands of the mucosa seem to be first involved, producing a felliculitis to be followed by gross ulcerations. As a rule, in all types of infection except the tuberculous and syphilitic, the inflammatory process is confined fairly well to the mucosa and submucosa, consequently while the bowel wall is thickened and more rigid than normal and may present a "gaspipe" appearance on an x ray plate, there is comparatively slight narrowing of the lumen and actual stricture is an exception. On the other hand, tuberculosis and syphilis, are typical examples of chronic productive inflammation and the connective tissue formed in large part replaces the musculature and in its contraction produces stricture. This is notably true of syphilitic ulceration and particularly so in the negro who is prone to form excessive scar tissue from any chronic lesion.

In amebiasis and chronic ulcerative colitis there is an ever present tendency to recurrence. This may occur months or years, as many as four years in some of my cases, after complete clinical relief. Hence it is essential to keep these patients under observation many years after apparent clinical cure. In fact, we never know when a patient is actually cured. From time to time direct inspection of the bowel should be made lest we miss a dire consequence of chronic ulceration of the mucosa, namely, the development of adenomata. They are a not uncommon sequel, are usually few in number, sessile and easily removed by forceps through the proctoscope. These small growths, *per se,* are of no consequence and but rarely develop into adenocarcinoma. Two instances of such transformation I reported at our meeting in New York in 1924, one in a colored man aged twenty-nine, with multiple prolapsus of the colon, the other in a woman aged thirty-two, who had had recurrent attacks of chronic ulcerative colitis for ten years, an adenocarcinoma finally developing four centimetres in diameter in the rectal ampulla. With such examples before us, it becomes our duty to remove all growths immediately upon their discovery, however innocent they may appear to be, for some of them may prove to be genuine precancerous le-

sions. The chief extraintestinal complication of amebiasis is abscess of the liver. As already stated, this is rare in this latitude, and I have met it in only three instances of approximately one hundred and fifty cases personally observed.

HEMORRHAGIC COLOPROCTITIS

This is a comparatively rare variety of bowel inflammation, usually occurring in young adults, but it may be encountered at any age. The etiology is not clear but its clinical course indicates that it is an infection of as yet an unknown nature. The process may be limited to the rectum, the rectum and sigmoid colon, or the entire colon may be involved, but it does not invade the ileum. With low involvement, there may be only five or six passages of blood daily, from the granular mucosa, constipation and protracted course. When the entire colon is implicated, bloody stools may number twenty or more daily; emaciation, weakness and anemia are progressive and, unless controlled, the termination may be fatal. In the acute cases proctosigmoidoscopy shows blood oozing from a mucosa uniformly inflamed and spongy. Hemorrhagic coloproctitis is to be differentiated from amebiasis, bacillary dysentery, multiple adenomata of the colon, and bleeding from a fungating neoplasm.

PROTOZOA

The protozoa infecting the intestines are classified on the basis of their mode of locomotion as:

1. Rhizopodia, typical of ameba, with locomotion dependent upon the pseudopodia. 2. Mastigophora, the flagellate, by a whipping movement of its filamentous protrusions. 3. Sporozoa, in the motile stage, by a vermicular movement of the entire body, and 4. Ciliophora, producing motion by its cilia (linthicum). In each group there are a number of species. The ameba has five, of which only one, the ameba histolytica, is apparently pathogenic. Five species of flagellate are known, the three most frequently found being Giardia intestinalis (also called Cercomonas or Lamblia), the Chilomastix mesnili and the Trichomonas intestinalis.

Opposing views are held as to their pathogenicity. Some investigators assert that a large percentage of persons harbor them and that they are harmless, while other observers consider them pathogenic. Their habitat is the bowel lumen and, as a rule, they produce no demonstrable lesion of the mucosa, although the Giardia may possibly produce ulceration. All of them, especially when in massive infestation, irritate ulcers of the intestine produced by other agents. The biliary passages and the appendix are apparently foci of infestation from which showers of reinfection may occur. No form of treatment has proved successful for their permanent eradication.

The Sporozoa comprise several varieties of Coccidia which are parasitic and most cases have been studied in Egypt.

The Ciliophora have several species, but the variety found most frequently in the large bowel, especially the cecum of man, is the Balantidium coli, measuring fifty to seventy m. in breadth. It is a specific parasite organism, producing ulcerative colitis and invades the tissues deeply. It is a natural parasite of the pig and man is its accidental host. It is seen most commonly in Russia, Finland and Sweden, but sporadic cases have been reported elsewhere.

ACTINOMYCOSIS

Actinomycosis is receiving considerable attention in the literature. According to Boestrom's theory, which is most generally accepted, it has its origin outside the body, the actinomyces being "capable of a dual existence primarily as a saprophyte in old soil from which it gains access to grains and grasses and through their medium becomes capable of infecting man and animals." In man its most usual habitat is the cecum and its spread is by continuity of the involved tissues and through the blood vessels but not through the lymphatics. Finding of the ray fungus is diagnostic. Four of thirty cases of pelvic actinomycosis recently reported by Helwig were of rectal origin. Last autumn I saw a girl aged nineteen with a brawny thickening of the anterior rectal wall of several months' duration, mild, irregular elevations of temperature and progressive loss of weight and strength. Laparotomy showed actinomycosis of the uterine adnexa. Autopsy in March, 1926, demonstrated wide extension beneath the pelvic fascia, and infiltration and ulceration of the rectum.

DIVERTICULOSIS AND DIVERTICULITIS

In recent years, as a result of x ray studies, autopsy and operative findings, diverticulosis of the large bowel has been encountered rather frequently. These herniations of the mucosa through the musculature may be an accidental finding, most frequently in the sigmoid and very rarely in the rectum. They may cause no clinical symptoms and be quite harmless. However, in certain cases, their stomata become so narrow that they do not empty completely. Inflammation ensues, producing a diverticulitis which takes an acute or chronic course. After eroding the mucosa lining the diverticula, the infection most frequently infiltrates along the mesenteric vessels or into the appendices epiploicæ. In acute diverticulitis an abscess may thus be formed which gives all the symptoms of acute appendicitis transferred to the left side, namely, pain, elevation of temperature, leucocytosis, local tenderness, etc. Unless recognized and relieved promptly by surgical intervention, the abscess may burst into the peritoneal cavity or rarely become adherent to another hollow viscous, as the bladder, and rupture into it. Usually, however, the infection pursues a chronic course, with production of connective tissue, infiltrating the bowel wall (perisigmoiditis), obstructing its lumen and forming a tumor having all the characteristics of a malignant growth. Indeed, even at operation, a chronic diverticulitis may so resemble a neoplasm that only histologic examination can settle the diagnosis. It seems probable that many cases of spontaneous cure reported after colostomy for a "cancer" of the sigmoid were in reality chronic diverticulitis. Thanks to improved methods of diagnosis, especially an x ray study, these errors in diagnosis are much fewer than in the past.

Local infections about the anus and rectum arise most commonly from a lesion of the mucosa produced either by a hard scybalum or a foreign body ingested, as a fish bone, or introduced per anum; unskilled use of examining instruments, or irrigation nozzles, or by prostatic massage. The latter fre-

quently initiates a proctitis and abscess may follow. The abscesses may be subcutaneous or submucous (mural) or in the cellular tissue beneath the superficial fascia. Of course, the most typical lesion is a fissure in the poorly nourished lining of the anal canal. Through this breach infection enters the cellular tissue to spread backward in the midline, forming a blind internal or complete fistula or laterly into the ischiorectal fossa of one side (ischiorectal abscess) and then across to the other fossa, eventually resulting in a horseshoe fistula. These are all quite evident on examination but there is another class of abscesses concealed from external signs, which are treacherous and dangerous if unrecognized. These are the deep pelvirectal abscesses located above the levatores ani muscles. They are extraperitoneal, produce chills, fever, pain and discomfort, at times retention of urine and leucocytosis, and a bulging in of the apparently intact rectal mucosa can usually be felt on digital examination. In one of my cases the picture was that of prostatic abscess with vesical retention but an unobstructed urethea and clear urine gave a cue to the correct diagnosis. Unless they open spontaneously into the rectum, the abscess in neglected cases may burrow upward and point in the inguinal region.

TUBERCULOSIS

Tuberculosis presents a separate and distinct problem. About fifteen per cent. of fistulæ are tuberculous and the infection is prone to spread in the perirectal cellular tissue, the cold abscess originating in tuberculous infection of the hip joint or tuberculous caries of the spine may point in the ischiorectal fossa.

From this cursory review it is evident that application of our present knowledge will enable us to diagnose correctly the nature and location of nearly all of the infections we encounter in the practice of proctology. However, the etiology and permanent cure of chronic ulcerative colitis remains one of the interesting problems in this field which still requires intensive study.

The Study of Rectal Diseases in America

J. F. MONTAGUE, M.D., F.A.C.S.

New York

Last year under the title of Rectal Surgery Abroad I contributed an article which consisted of a survey of the various rectal clinics abroad and the opportunities offered there for special postgraduate instruction in proctology. In response to this I have had fairly numerous requests for information, curiously enough not about postgraduate instruction abroad but about similar opportunities here in America. It naturally occurred to me that an article presenting such data might be of service not only to those who have written me, but also to the many mute inquirers who, I am sure, exist.

The establishment of the speciality of proctology, or the study of rectal diseases, is not nearly as recent in its origin as one might infer from the relatively few men who have been shrewd enough to establish themselves in the field for the fact remains that at the present time it is the one and only uncrowded speciality. In consonance with this view are the remarks made by Ralph W. Jackson, M.D., F.A.C.S., in his presidential address before the American Proctologic Society. "Obviously proctology is the great underworked field of specialism of the present day." "Any one of the cities of fifty to one hundred and fifty thousand could well support one (a proctologist) and even lesser and more remote communities which are important business and railroad centres, could do the same. They draw from their tributary territory patients seeking first class advice in surgery, medicine and the other specialties, and why not proctology? I believe that I have underdrawn rather than overdrawn the opportunities these cities offer, and that they are beckoning for at least as many, and perhaps more, men than I have suggested to grasp them."

There are, of course, reasons for this sparsity of attention which has been accorded the specialty by the medical profession. Chief among these is the fact that proctology is the latest branch of medicine to emerge from the low state of development which characterized the practice of medicine some fifty years ago. This statement does not impugn the sincerity nor the relative ability of these early practitioners but merely seeks to call attention to the fact that medicine in the nineteenth century was, in this country as elsewhere, a very loosely organized profession which countenanced or tolerated practices which are today sourly frowned upon as quack or illegitimate methods.

Another factor which I believe we must be frank to admit is the unreasoning antagonism of the general surgeon to any of the specialties. The experience of all the specialties has been alike; the nose and throat specialty, the orthopedic specialty and more lately the urological specialty. Each has had to contend with a type of petty selfishness which reveals many of our socalled great surgeons as poor puny mortals whose instinct of selfish greed lies hidden but not smothered under the mantle of greatness. These are the men who try to convince us that it is futile and absurd for any medical man to devote himself exclusively to but one class of disease. Yet if this same "all around specialist," the general surgeon, were to require the fixing of his watch, you may be quite sure he would take it to a jeweler and not a plumber, notwithstanding the fact that both are mechanics. However much we may like the mold of age and revere the dust of tradition, yet if we are at all fair minded, we must admit that the trend of thought and training in our

present day is entirely along the lines of specialization. Surely that doctor who continually sees fifty cases of rectal disease a week or even in a month must be very dull indeed if he does not know more about these diseases than the doctor who sees perhaps a few such cases a year. Indeed if justification of this specializing tendency were necessary we need not look further than the physiology of our own bodies. Here we see how a single cell, the ovum, becomes a mammoth mass of cells, not identical each with one another, but constituted into an organism comprised of many different kinds of specialized cells and cell units which by their efficiency along their particular specialized lines make possible that higher form of functional life, namely, intellect; found in every human being, and used by some.

The medical schools have until lately given little if any attention to the teaching of proctology, and this has been unduly criticized by the proponents of the specialty, yet a little investigation and reflection on the state of medical education will be sufficient to make one aware of the fact that the curriculum of the modern medical school is at best a very crowded affair. This crowded condition is due to the expansion of the fundamental sciences and these certainly should be given precedence over a highly specialized study such as proctology. The special study, therefore, of rectal diseases is one which has come to be considered a purely postgraduate course. This, indeed, is as it should be because there can be no question as to the importance of the basic medical studies. That the medical schools have been very generous may be inferred by a study of Table II. in which it will be seen that in the majority of medical schools listed, instruction in proctology is given as an undergraduate study at the expense of time which might better be used for the basic studies.

Perhaps the chief reason that proctology has lagged in its development, is the fact that it has had no apostle who had sane convictions on the subject, combined with the courage of these convictions. No specialty can expect to evoke much less command the respect of the general medical profession, as long as it tolerates the utterance of medical nonsensities at its scientific meetings. As long as these meetings are replete with weird ideas on pathology, chemistry and ordinary high school physiology, the cause of proctology will suffer. One would hardly think it pos-

The author will be glad to correct omissions or errors in a future article.

Total number of clinics, 23; states represented, 12; graduate, 10; undergraduate, 13.

sible to hear one of the acknowledged leaders in the field cast doubt on the etiology of syphilis, to hear it said that suger is excreted through the sweat glands, or to hear equally fantastic statements made in regard to bacteriology. Truly the specialty needs a man who will tell the truth even if he gets hurt for doing it.

Despite, however, all the handicap which the above mentioned situations create, it will be noted that the specialty has grown both in size and in popular favor. Thus in conjunction with gastroenterology proctology was granted a special section in the American Medical Association as far back as in 1916. The American College of Surgeons now admits to its ranks Fellows who devote themselves entirely to rectal surgery. Numerous books on the specialty have been written by men who devote their entire practice to these diseases. Fifty-two special rectal clinics exist throughout the United States and the subject is taught in twenty-three grade A medical colleges. With these facts fresh in mind we can certainly agree with the book reviewer of *Surgery, Gynecology and Obstetrics* in his comment, "There seems to have been quite an impetus given to the study of the diseases of the rectum and colon in the recent past." For the information of those interested as well as for the sake of substantiating my statements made in previous paragraphs, I submit herewith two tables showing the location and some incidental data relative to the various rectal clinics and opportunities for the study of rectal diseases in the United States.

The accompanying tables are admittedly very incomplete, but it is by far the most complete compilation available at this time. Indeed, it is the only such collection of information. It is to be hoped that those readers who are possessed of information lacking in the data submitted herewith, will be kind enough to send in such additional data for the future revision of the statistics here presented. Much of the information given in these tables has been obtained from the members of the American Proctologic Society during the two years I was secretary treasurer of that society and for their cooperation I am deeply grateful.

The data presented in the accompanying tables may be briefly summarized as follows: There are in the United States fifty-two clinics devoted to the treatment and study of rectal diseases; these clinics are widely distributed throughout the states, seventeen different states being represented in Table I. Nearly half of these clinics are conducted as distinctly specialized departments; in the remainder the department is a subdepartment of general surgery. From this fact I believe that we are justified in drawing the inference that proctology is receiving an increasing recognition as a specialty. This conclusion appears to be supported by the fact that of the twenty-three proctological courses (Table II) being offered throughout the country over half of them are being given to undergraduates in their senior year.

I have left for final mention what I consider the most important reason for the slow spread of knowledge on the subject of rectal diseases. I believe this reason to be that no attempt has been made to improve our methods of teaching this subject. I, personally, have made such an attempt and it has proved very successful in my hands. I have no doubt that when petty pride and prejudice have dwindled to the extent of allowing others in this field to imitate me, it will

be found equally advantageous by them. My method of teaching is extremely simple, practical and yet complete.

To explain the working of this method let us take the viewpoint of a physician who, because of the rigors of general practice, has decided to do more efficient work along one special line and at the same time get more out of life. The most logical thing for him to do would be to visit the clinics of men who are giving special attention to rectal diseases. Naturally he would come to New York because of the unequalled clinical facilities and the number of special clinics held here. He would journey from one clinic to another seeing what cases happened to come in; perhaps seeing many cases of the same type within the same few days but it would be quite obvious, even to a beginner, that such a method of study is, to say the least, haphazard. It is quite as likely to remain in your mind as a mass of vague impressions, because of the unsystematic manner in which these impressions were obtained. Not only is every impression but fleeting and superficial, but the total of these impressions is not of impressive value in thorough study. The area under examination is, at best, but six inches square and when this is encroached upon by the presence of operating hands and instruments, one cannot reasonably expect very much view at the distance required by a seat in the amphitheatre of an operating room.

With these facts in mind and with an infinite faith in the future of the study of proctology, I planned a very definite series of lectures to cover the entire subject of proctology. Were this all that I could offer, no advance would be made over existing teaching methods. There would still be the great drawback that students object to, that of being "talked at," rather than shown. In order to show the conditions of rectal diseases both in the gross and microscopically, as well as to demonstrate in detail every phase of treatment, I conceived and produced an entire series of motion picture films aggregating 55,000 feet of film. When these pictures are thrown on the screen, the perianal region is seen as an area nine by twelve feet in size. Accurate observation of the conditions portrayed is not only possible, but, in truth, cannot be avoided. Explanatory animated drawings supplement a showing of the actual condition. Finally, motion pictures of the operation on an actual living subject are shown and the treatment summarized and tabulated.

This procedure is followed in the subjects outlined below and is supplemented by personal explanatory talks whenever students desire them. A brief outline of what is offered is shown herewith:

BASIC PROCTOLOGY (INTENSIVE COURSE)

1. Anatomy and physiology of the rectum and anus.
   Dissections of pelvis, perineum, rectum and anus supplemented by animated charts and diagrams.
2. Methods of examination and instruments used.
   Demonstration of diagnostic methods, and of instruments in current use among proctologists. Moving pictures.
3. Rectal and anal abscesses.
   Varieties, appearances, diagnosis and treatment illustrated by animated diagrams and operations illustrated by moving pictures. Simple evacuation, procedure in tuberculous cases, scalping operation for abscess, etc.
4. Anal and rectal fistulæ.
   Relation to abscesses, diagrammatic explanation by moving pictures—treatment; operative, injection with pastes, dressing of wounds, cases, healed wounds, etc.
5. Fissure in ano.
   Descriptive moving pictures, appearances, cases, diagnosis, treatment: transcision, excision operation, subinjection methods, etc.
6. Hemorrhoids.
   Cases, classification, method of treatment explained and illustrated by motion pictures; ligature operation, clamp and cautery operation, injection methods, radium seed method, etc., histological study.
7. Pruritus ani.
   A thorough study of the causes, the tissue changes and the adequate treatment of cases demonstrated and explained by moving pictures, animated diagrams and moving picture microphotographs.

ADVANCED PROCTOLOGY (INTENSIVE COURSE)

1. Embryology and malformations of the rectum and anus.
   Practical applications of the embryology of the rectum to the explanation of malformations. Explained by animation.
2. Prolapse of the rectum.
   Cases, symptoms and the pathology of the condition. Explanation of the cause and mode of production of prolapse. Moving pictures. Treatment.
3. Cancer of the rectum.
   Histological study, operative methods of treatment, excision of the rectum; treatment by radiation and by radium. Moving pictures, photomicrographs.
4. Referred pains of rectal origin.
   Practical importance of rectal conditions causing misreferred pains. Explanation of certain cases of backache, lumbago, sciatica, etc.
5. Stricture of the rectum.
   Causation, histological study, effective treatment. Operative methods — proctotomy, dilatation. Carbon dioxide snow method of treatment. Moving pictures.
6. Miscellaneous rectal ailments.
   Cryptitis, papillitis, incontinence, etc.
7. Anesthesia in rectal operations.
   Demonstrations, discussion of relative value of general anesthetics, local anesthetics and the method of sacral and spinal anesthesia. Moving pictures.
8. Rectal surgery abroad.
   Hospitals abroad, proctologists abroad and methods used. Some miscellaneous notes on the successful practice of ethical proctology.

I trust the statistics and information submitted in this article will be found of value to those seeking information on rectal clinics, courses in proctology and the status of the specialty of proctology in America.

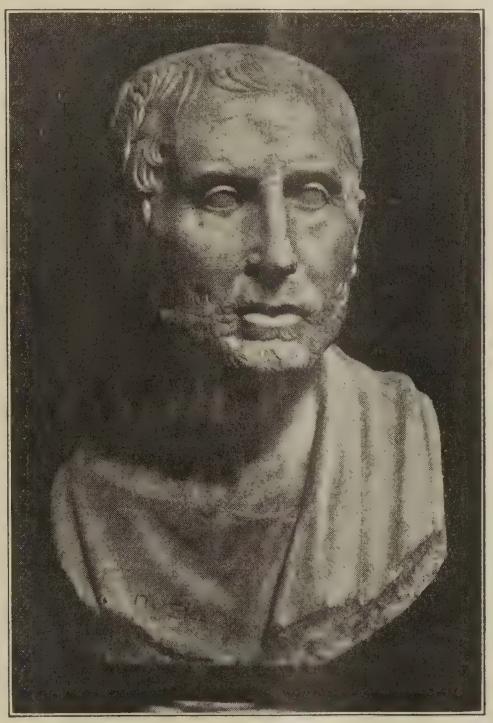
Historical Medicine

The Legacy of Greece to Galen

III: *Its Utilization*

JONATHAN WRIGHT, M.D.,
Pleasantville, N. Y.

In the previous papers of this series in a very general way we have been concerned with the antecedent material on which Galen built his superstructure of experiment and theory, the roots of his anatomy and physiology nourished in the soil of Greece and watered by the genius of its philosophers half a thousand years before him. In his book on the dogmas of Hippocrates and Plato (1a) we gathered something he had to say about them, but there, too, we catch him at his task dispelling the mists of the centuries while revering the prophets and paying tribute, not always respectful, to Aristotle. Hippocrates was perfect as far as he went, but Galen with a sort of Asiatic obsequiousness and suppleness before an idol, carried him further in the direction he thought he ought to go than the physician of Cos ever intended to go, perhaps somewhat as Plato did Socrates. Plato left Socrates to us an incomparably lovable figure, a mighty monument in philosophical thought, and Galen only in a less striking and complete way did much the same to Hippocrates. He often pays honorable tribute to Aristotle, whom he however often refutes. He never mentions Hippocrates but to praise him. Yet I can never avoid thinking of Galen rather than of Hippocrates as the outstanding figure of the beginning of modern medicine. Hippocrates seems to fuse into Æsculapius as the hero of a bygone day. His mind has a clarity we do not always observe in Galen and Galen frequently grovels on the earth before a current superstition or an ikon of his own making. Hippocrates never does, but he is distinctly a figure of the past, a legacy of Greece it is true, but a legacy nevertheless. Galen (1b) refers to Plato in the *Timaeus* establishing the hypothesis or accepting it of a single primordial substance or matter (Stoicheion), a common element into which all the others could change, and refers also to Thales, Anaximines, Anaximander and Heraclitus selecting a different element for it. They all seem to dream of a common element, but it is of the one whose phenomena of changes of form have struck each one most impressively. They contradict rather than support one another and no one of them is convincing. Whatever Galen may think this is something which impresses us agape before another kind of monism.



Poseidonius, Naples, National Museum (*after Hekler*)

Into this we have already penetrated in a shallow manner, but sufficiently. The qualities of matter, however, are more intimately associated with medical thought, especially clinical medicine, for it is by virtue of the qualities that we make our diagnosis. Heat it is true qualifies other matter but when it qualifies the animal body we are interested. There were those who insisted the senses not only took cognizance alone of the qualities, but that was all there was to it. There was no reality in the way of matter. Of course Galen rejects this, but he seems to regard this as scarcely more outrageous than asserting that the elements have no qualities (1c). He thinks he has shown there are elements of matter four in number and no more and four qualities only, or at least nothing but those designated by insensate homonyms and he desires the reader to make no mistake about that however much he may relate the belief of others. An element is an element whether isolated or not and it is always the same. Qualities are different, there may be more or less of the hot or the moist. Fire, however, was a stumbling block. There was air and earth and water, but fire was the hottest heat, Galen had to admit. Here an element surely seemed to merge into a quality, just as energy and motion seem to merge into matter much to our own confusion. However he was not disposed to consider water as the wettest wet. Water and earth could not be denied existence, but why was fire anything but the hot? This sort of a quandary Athenæus put him into when he was only nineteen. It was up to him to admit heat was as much of an element as a hot bath. It bothered him very much then, but he apparently learned to bluff later on. "It is not up to me to clear up your sophisms. Clear them up yourselves." But further on in order to get rid of the conception of matter as without attributes there seems an endeavor to share the argument of Athenæus that the element and the quality or the combinations of qualities are all one whole. This seems to shelve the idea of one underlying element, a fundamental monism, but it leaves us in doubt

how Galen is going to get along with this conception in his humoral doctrines. At least we only know matter by its attributes. That seems clear to us. On the whole Galen thinks this preposterous, at least that we can take nothing out of a body without putting something in the place of it and he seems to us to be getting deeper in the mire, having rejected the idea of one primordial element, when he says (1d) or seems to me to say: "Air, fire, water and earth do not have their origin in other bodies, but from the whole (or matter?) and the qualities." If this is not a sophism, it seems something still more absurd and we must leave him to clear it up and turn from this rather unprofitable supplement to my former essays to understand his elementary principles and plunge into matters of more immediate medical interest.

We find him in the midst of it at the point (1a) where I digressed to former interests. He quotes from Nicander the idea of the view that cardialgia was an affection of the heart, but far back of Nicander we could find traces of the belief that not only drink but food passed into the heart when "the heart" vaguely meant the belly. He insisted that physicians wrongly interpret the word as indicating that the symptom has its origin in the heart. He says all the symptoms point to the orifice of the stomach and cardialgia is a misnomer, but we soon get on the track of the notion of Aristotle and many others that the heart is the seat of thought. Galen hesitates at the palpitation of the heart arising from fear, but if it is so this doctrine is not due to the Peripatetics and the Stoics but to Hippocrates and Plato. He is quite sure any movement of the soul is due to the action of the mind and the mind is not located in the heart. "It is not as Aristotle and Chrysippus but as Hippocrates and Plato teach." The beginning of our impulse to voluntary motion is in the brain, but certain other and involuntary motions have their origin from the heart. We see then that however well he knew the share the afferent and efferent nerves had in the mechanism of motion, he recognized there were other nerve actions which might originate elsewhere. Reflex action and its congeners, if they must insist upon it, can not be attributed to the brain. Here is the faint germ of the perception of a sympathetic nervous system separated from that of the brain and its immediate appendages and it was far into modern times before we did much more.

This might well have resulted from the series of experimental observations upon animals narrated by Galen as to nerve currents and blood currents, but the neatness and completeness of his accounts rather argue that some at least of the original work did not originate with him but before him. Into the details of this I of course can not here go, but I have referred to it elsewhere on several occasions in comments on other treatises of Galen, where it is more fully set forth. In this connection though I may advert to the high opinion Galen had of the anatomical knowledge of Hippocrates and the Asclepiades, higher than he gives any specific proof of. The work on the veins in *The Nature of Man* has been acknowledged even by him not to be a genuine treatise and Aristotle quotes it in the *History of Animals* from Polybus, a son in law of Hippocrates, but Galen and others before him, he says, think (1e) that part of it was written by neither. Why Hippocrates should be quoted by him as an authority for the origin of the veins from the liver and why Galen gently chides (1f) Plato for not following Hippocrates elsewhere in the *Nature of Man,* is explicable only on the view that independently of this Galen had a very high opinion of the anatomical knowledge of Hippocrates and somewhere he also refers to the training the sons of the Asclepiades got in anatomy from their preceptors. It is a little strange that such high value should be placed on the anatomical learning of Ancient Greece by such an anatomist as Galen in the second century A.D., who says that not only he alone, but other anatomists, in fact all, have shown the nerve supply originating from the spinal cord and that from the brain. Such anatomy as we have any knowledge of the Greeks' possessing in the time of Hippocrates might well move the contempt of the school of Alexandria at that date and incite such a critic as Galen to the vivid expression of it. Either these ancient Greeks possessed far greater anatomical knowledge than we know of or it is a most striking example of reverence in Galen, the man of vituperation, for the Master.

Elsewhere Galen says Herophilus and Eudemus, living more than a hundred years after the death of Plato, first clearly differentiated the nerves. Then in his ardor to give Hippocrates more than his due and at the expense of casting a shadow on his other idol—Plato—he exhibits self contradiction if he does not consciously misinterpret facts for the strengthening of his argument, but it needed only the breath of a tradition for Galen to ascribe wisdom to the former. I have alluded to his vacillation about some of the phenomena of the sympathetic nervous system. The heart indeed palpitates with fear and with love as Hippocrates understood in the story of Prince Perdiccas in love with his stepmother, a tale even then also told of Erasistratus and some princely patient of his. It seems to us in view of what he says about cardialgia that he places the cardiac evidence of these emotions in the same class. Objects first cognized by sense—of sight, hearing—exciting love or hate or fear— and a more rapid heart beat do not seem even to us, knowing so much more, to go very well with heart burn from a sour stomach. On placing them on a level it is no wonder Galen falters. Perhaps, he seems to think, emotion is motion of the heart primarily, but the exciting cause being first perceived by the reasoning faculties and the nerves of sense which feed them with cognition in the brain must have staggered him and the opinion of Hippocrates only kept him in error, but he evidently was in doubt too. Aristotle was in greater error and less doubt. He believed we thought with the heart and the blood. As a matter of fact Plato was leaning far nearer the truth with his tripartite soul. He was striving toward a theory to cover all the facts. If he knew anything of the cerebral nerves we have no clear evidence of it, but the brain was the seat of cognition and reason, the heart that of the generous passions, the liver of the evil, and the blood played the part of the nerves. The brain was the acropolis where Athena dwelt, the temple of emotion was in the heart and the seat of lust in the liver below the diaphragm.

We follow the flitting of these thoughts and they do not leave us altogether cold and they evidently moved the thought of Galen much more deeply.

Eventually Galen's work on the nerves and that of his predecessors banished these things from anatomy, but it was not until the sympathetic nervous system found a place in it that physiology passed from under a cloud and it is not all plain sailing yet. Here in this book on the dogmas of Hippocrates and Plato Galen reviews the evidence, elsewhere exposed in detail, of the origin of all the nerves in the head and brain and makes it a parallel with the arteries starting from the heart, the veins from the liver, and we see the thought of Plato's tripartite soul supporting the parallel in his mind. They were distinct in function in the government of the body. There was no interchange of function. Pressure on the brain paralyzes, but the heart beats on. Pressure on the heart does not paralyze movement or volition. Not as others, on argument and high flown theory, Galen boasts his opinion based on experiment and observation. In other words, he makes the same reproach and with more reason on the work of his predecessors by four or five hundred years as Vesalius and his followers cast on Galen, but far more than he knew he was in thrall to the legacy he had from Plato. It is apparent there was call for acute analysis to ascertain an exact nomenclature to fix the thought of the beginning of emotion in the arrival at the brain of the image exciting it. The "soul" no longer sufficed and the still mystic appellation of the consciousness had not arrived.

Some one of the Peripatetics, according to Galen (1g), suddenly appeared saying the emotions are carried up from the heart, where we infer he thought they began, to the brain by certain membranes stretching between them. For this opinion possibly Aristotle was not responsible, but it indicates the influence of the theory of an abstract something requiring a lodging place, countenanced by his indicating the heart as the source of emotion. This no doubt retarded the acceptation of the nerves as the channels of impulse to action from the brain and as the paths of external impressions. Poseidonius, whom Galen calls the most learned of the Stoics, repudiated much of the doctrine which went to such extreme lengths in the works of Chrysippus, two hundred years after Herophilus, in the time of Ptolemy 1st (300 B. C.), had demonstrated the difference between nerves and fibrous structures. Poseidonius was an older contemporary of Pompey and Cicero, the latter of whom often speaks of him with great respect. Nevertheless he still upheld (1h) the tripartite soul of Plato and apparently believed in augury when the augurs themselves had long since begun to smile at it. In the wording of Plato he speaks of these souls as the seats of important powers, but we find Galen two hundred years later practically only recognizing the brain, heart and liver as organs in which important physiological actions were located, the "secretion of thought," the mixing of the pneuma with the blood and the sifting out of the secretions. It is thus we mark the advance of thought and it was a great step forward and we find it in Galen first swinging into line with modern medicine. Galen then was profoundly influenced by Platonic thought and though guided by it he was yet veering in the right direction.

Although Galen is never disposed to neglect this Platonic tenet and keeps in view the pneumatic theory, one of his greatest services to physiology was his repeated denial of the claim of Erasistratus that the arteries contain only the air and the pneuma in it and this denial he supported by the most convincing experiments, but out of that conception of the pneuma, supported by the observation of the change of the color, the oxygenation of the blood in the lungs, another fundamental principle of modern physiology, got its start. Why the discovery of the true course of the circulating blood had to wait fifteen hundred years, despite the legacy of Greece as it was multiplied by Galen, is to be sought in the wider study of the history of cosmic events. The discovery of the cardiac valves has been ascribed to Erasistratus, but some historians seem to doubt if he did more than describe the chordæ tendinæ. That would indicate the auriculoventricular valves only, but it is difficult not to recognize in the reference (1i) of Galen, that he noted the others. Whatever his idea was perhaps he needed them as much for the circulation of the pneuma as Galen did for the circulation of the blood, but we may end here with the remark of Galen correcting Aristotle: "It is *not* because the arteries are filled with pneuma that they are dilated and throb."

Guaca Digging

WILLIAM COLBY RUCKER, M.D.,

New Orleans, La.

Guaco is a Spanish word which came into use after the discovery of America. Probably it was a native word picked up by the *Conquistadores* in much the same way as we of North America incorporated succotash, hominy and pemmican into our dialect. Be this as it may, *guaco* throughout Latin America means a grave, more particularly an ancient pre-Columbian burial place and the feminine, *guaca* means anything found in such a grave.

It may seem at first glance that ancient graves and their contents are very remote from the field of medicine; that the archeologist may receive a thrill from grubbing up the sepulchers of a forgotten people but that graves, even though they are prehistoric, would be of small interest to the medical man. There is a great thrill when one holds in his hand a golden ornament, a beautiful pot or a stone chisel which no other hand has touched for perhaps

a thousand years. *Guaca* digging is a wonderful sport in that it is a wonderful stimulant to the imagination. One pictures the crowd of mourners reverently laying to rest the body of some chieftain wrapped in mantles of feathers and skins: his weapons, pots containing food and his choicest ornaments are placed beside that still body ready for the long journey; stones are swung into place: the earth is filled in while the medicine man chants charms to speed the traveller on his way; some nearby rock perhaps is marked with hieroglyphs looking like a rude sketch map. Then you come hundreds of years later to find that no trace of the body remains and only gold ornaments and baked clay are left to show where once a man went over the horizon's rim.

In Central and South America there are many large collections of graves. Usually they are discovered quite by accident but occasionally there is a marked stone in the center of the cemetery. Costa Rica and the western provinces of Panama have many of these burial places and as they are not protected, it is usually easy to prospect for *guacas,* in fact, many natives open graves as a side line in the hope of finding gold in them.

Little is required in the way of equipment, a crowbar, a shovel, an inevitable machete and a good stout native who will dig all day for a dollar gold, being all that is necessary. In looking for grave sites the *mozo* can usually tell about where to commence the search. Usually they are somewhere near big flat stones into which spirals, whirls and running figures have been cut. Having located on a likely spot, the *mozo* begins thrusting the crowbar into the earth until a stone is struck from six inches to a foot beneath the surface of the ground. From this as a starting point, the crowbar works radially in every direction until a rectangular layer of stones has been mapped out. Usually this area is about three feet wide and seven or eight feet long. Having marked the corners, the earth is removed until a layer of flat stones is exposed. As a rule, especially in the Chiriqui country around Boquete Bajo, these are flat water worn stones. These are removed and a trench is sunk. About three feet further down, a row of stones is struck on one side of the trench. As the excavation continues, these become more and more apparent and it is seen that these are good sized stones standing on end and chinked at the top with small flat stones. These should be left in place until the digging has been completed, i. e., until the bottom of the lateral stones has been reached. These stones are about fifteen or sixteen inches long and are more or less triangular on cross-section being about five or six inches on a side. Behind them is the grave itself. In the Chiriqui, the bottom of the grave is a rather hard white stone, a natural layer, called locally volcanic concrete.

The chinking stones are carefully removed and one by one the bigger rocks are gotten out. Behind them is then seen a little cave, strangely reminiscent of a lower berth on a Pullman. In the bottom of it is a layer of moist earth from three to six inches deep. Using the hands, this is now scraped out with the greatest care. Every bit of it must be searched because sometimes the gold *guacas* are not any larger than a pea. In a moment a pot is felt. The earth is carefully removed from around it and with greatest care it is lifted out and set in the sun to dry when it may be handled with less danger of breakage. Little burnt clay figures two or three inches in height, whistles shaped like birds, figures of animals, stone tools, jade beads and amulets are frequently found but of human remains not a vestige, not even a tooth, is encountered.

The study of the *guacas* removed from these ancient graves is intensely interesting and serves to throw considerable light on the customs and beliefs of the forgotten, nameless people who buried them. Many of them show a considerable advance in art and craftsmanship and the amount of gold and copper found indicates that mining in these metals was fairly common. The presence of jadite which came from Mexico and turquoise which came from the ancient mines in New Mexico in a tomb in Panama warrants the presumption that at that remote time there existed a commerce which extended from the continental United States into Panama.

Gold *guacas* exhibit a wide variety of shape, size and design. Crocodiles and jaguars from one half to one inch in length, human figures from one to three inches in height, fish, eagles, frogs from one to six inches long, beautifully chased breast plates shaped like eagles or circular like those found in the ancient Irish and Norse tombs, armlets, legbands and a great variety of other pieces of jewelry are found. Bells exactly the shape of the old fashioned sleigh bell and varying in size from a small marble to a goose egg are not infrequently met. For the most part the gold is the softest, virgin, yellow gold but sometimes it is alloyed with copper or has a base of copper over which a thin layer of gold has been spread. It has been held that these latter were of Spanish manufacture and were traded by unscrupulous *Conquistadores* for articles of virgin gold. On the other hand, alloyed and plated bells have been found in graves which are apparently as old as those by which they are surrounded. All of the gold *guacas* are well modelled. Sometimes the figures of birds are conventionalized, usually the frog, crocodile, jaguar and human figurines follow nature fairly closely. The socalled slave or captive *guacas* show a human figure attired in a loin cloth and headdress or possibly a crown and bound by ropes to a pillar on either side. Sometimes there are two figures and three pillars. The detail is exquisite.

The objects of burnt clay consist largely of bowls and pots of various sizes. Some of the bowls have a handle; many of the pots have two little protuberences, apparently designed to prevent the lifting fingers from slipping. Generally, the pot is ornamented with the whole or part of some animal or fish. It is thought that these perhaps represent some object of worship. The armadillo in whole or in part, conventionalized or natural, is frequently depicted on this pottery. Sharks and crocodiles are also used and in the bisque pottery, the monkey with a ceremonial bar across his arms is almost always found. These monkeys have their hands over their ears, mouths or eyes exactly like the "hear no evil, speak no evil, see no evil" specimens so often seen in the Chinese curio shops. Pots have round bottoms or stand on three legs or an open work ring of clay. The legs are commonly hollow and contain a little bell of baked clay. They represent shovel nosed

sharks, armadillo heads and other animal life or they may be simply ornamented with a row of holes and little line border. Water jars have a relatively small opening (some have two) standing on a constricted neck. Cooking dishes have wide mouths, some being broad and shallow, others narrowed and deeper. Many are ornamented with red, black or green pigment in designs showing twined serpents, conventionalized crocodile heads and triangles containing a number of round dots. Sometimes stone vessels and vases are found, also stone seats. In certain situations all clay vessels found have holes punched in the bottom. This is believed to have been part of the funeral rites.

The burnt clay figurines are especially interesting and there is a splendid collection in the National Museum at San José, Costa Rica. From them may be obtained considerable information of these ancient peoples. Some of these are decorated in colors and pierced, evidently to admit of the passage of a string so that they may be worn suspended from the neck. Once in a while a figure represents some deformity, for example, at Cartago, C. R., I saw a figurine of a hunchback. The spinal curvature was probably due to an accidental fracture of one or more vertebræ, since tuberculosis, the usual cause of such deformities, is not believed to have been a pre-Columbian disease. Not infrequently the pottery whistles are made in human form, frequently showing some disease condition. Perhaps these were used by the medicine men in their curative incantations. One of the most interesting of these whistles which was found represents a woman in the act of parturition. It is remarkably well modelled and the face expresses, with considerable fidelity, the pain which she is undergoing. Along the sides are several holes. These are evidently arranged for the fingers, so that different notes may be blown on the whistle. It is not inconceivable that this was used by the medicine man as a part of his incantation during labor. There is a collection of these figurines at the National Museum at San José. Study of these might throw considerable light on the medical practices of these primitive people.

The material used in making clay *guacas* varies from dark to light red and dark slate to biscuit color. Of the pots, the most beautiful lines are seen in the bisque ware which exhibit as great skill as if made with a potter's wheel. Some of the tripods compare favorably in line and design with the ancient Grecian vases. The surface finish varies from the somewhat rough bisque to the very smooth of the deep red objects. Some of the figurines seem to have been coated with some sort of a glaze.

A Sixteenth Century Precursor of Alexis St. Martin

CHARLES GREENE CUMSTON, M.D.
Geneva, Switzerland.

Matthew Cornax, in his book entitled *Medicæ Consultationis apud Aegrotos Secundum Artem et Experientiam Salubriter Instituendæ Enchiridion,* published at Bale in 1564, relates an interesting case of gastric fistula which I will briefly summarize.

A peasant of Bohemia being out hunting was accidentally hit by a pointed stake in the region of the stomach, giving rise to a very large wound. The patient's condition was regarded as fatal because to all appearance the wound could not be closed by any known means. Yet contrary to the prognosis of the attending physicians, the edges of the wound became hardened to such a degree that the rustic was able to pack the gastric wound with lint with such skill that whenever he wanted he could clean out his stomach through the opening into the viscus, withdrawing the juices and food contained in it. This man survived a number of years.

A word about Matthew Cornax, as he is little known in medical history. He was born in Romangna, studied medicine at Venice under the famous master Nicholas Massa, and himself taught medicine for some time in that city. Afterwards, this distinguished practitioner was called to the University of Vienna as professor and became physician to the emperor Ferdinand I of Austria.

Cornax also wrote a little work entitled *Historia Quinquiennis Fere Gestationis in Utero, Quoque Modo Infans Semiputridus, Resecta Alvo Exemptus sit, et Mater Curata Evaserit,* Vienna, 1550. It contains an account (as the title indicates) of a successful Cæsarean operation on a woman who for five years had carried her product of conception. This curious case is worthy of notice and we will give a short summary of it.

Margaret, twenty-five years of age, the wife of the landlord of the "Red Crayfish," a tavern in Vienna, had been previously delivered of several children, again became pregnant in the year 1545. She felt fetal movements as usual, but when at term she could not be delivered. She carried the fetus for five years and then the child was expelled into the abdominal cavity, the walls of the uterus having undergone necrosis. A large tumor developed and in consultation, Cornax advised making an incision in the mid-epigastric region. The physicians and surgeons present were unable to believe that the abdominal tumor was produced by a child as the patient had experienced peculiar pain for some time and also because five years had lapsed since she was pregnant.

However, the operation was carried out and a child was removed in such a fair condition of preservation that its sex (a male) could be made out. Recovery was uneventful. In a year the patient again became pregnant and went to term uneventfully, but could not be delivered. Cornax being called, advised the Cæsarean operation, but the patient's mother and other shrews present, would not hear of it, so Cornax and the surgeon who had performed the first operation withdrew. The woman died shortly after and then Cornax and the surgeon were hastily summoned and delivered by abdominal incision a fine male child which would have been extracted living had their advice been followed.

Editorial Articles

THE GENESIS OF GENIUS

We prate much about the sound mind in the sound body, but, if the brain be left out of account, the vigorous mind is about as likely to be housed in a shack as in a mansion. To be more truthful, we would better modify our aphorism to speak of a better mind in a better body, but this does not preclude the frequent finding of a feebler mind in this same stronger mechanism.

A very elaborate study of the mental and physical traits of a thousand gifted children, made by Dr. L. M. Terman and others, has just been issued, and the comparison of the physical characteristics of this group with control children of the same age gives interesting confirmation of the above thesis.

In their "health and physical history" the gifted children excel on the average the unselected in everything except vision, there being more cases of inferior eyesight among the mentally superior. This is in line with the findings of the Russell Sage Foundation in its study of defects of school children in New York City. As the gifted child reads two to three times as many books as does the ordinary child, there would seem to be strong evidence that this excessive use of the eyes for near work is disastrous, for it is not conceivable that poor vision should accompany genius any more than defective hearing or breathing. Those who make much of the effect of mouth breathing on school progress will be surprised to find many mouth breathers among the gifted, though fifty per cent. more cases are found among the control children and three times as many which are "marked" or "extreme."

"In physical growth and in general health the gifted group unquestionably rates on the whole somewhat above par. There is no shred of evidence to support the widespread opinion that typically the intellectually precocious child is weak, undersized, or nervously unstable. In so far as the gifted child departs at all from the average on these traits it is pretty certain in the other direction, but the fact seems to be that his deviation from the norm on physical traits is in most cases very small indeed in comparison with his deviation in intellectual and volitional traits. Even the slight superiority that he enjoys with respect to physical equipment may or may not be due primarily to endowment. It might be accounted for mainly if not entirely by such factors as diet, medical care, and other environmental influences.

"Two possible environmental causes of the intellectual superiority of our gifted group are definitely excluded by the data that have been presented: 1, formal schooling, and 2, parental income. It has been shown that within a given age group, the intelligence and achievement scores earned are totally uncorrelated with length of school attendance. The median family income does not greatly exceed that for the general population of the cities in question. The families of some of our gifted subjects are in financial circumstances below the level of moderate comfort.

"In a majority of cases the superiority of the gifted child is evidenced at a very early age. Among the most commonly mentioned indications are intellectual curiosity, wealth of miscellaneous information, and desire to learn to read. The frequent presence of such traits among our subjects in the preschool period suggests strongly the influence of endowment. Although in a small minority of cases attempts at forced culture may have contributed to the result, it is manifestly impossible to account for the general superiority of the group by any such influence.

"There are, nevertheless, many persons who believe that intelligence quotients can be manufactured to order by the application of suitable methods of training. There are even prominent educators and psychologists who are inclined to regard such a pedagogical feat as within the realm of possibility, and no one knows that it is not. If it is possible it is time we were finding it out. Conclusive evidence as to the extent to which the IQ can be artificially raised could be supplied in a few years by an experiment which would cost a few hundred thousand or at most a few million dollars. The knowledge would probably be worth to humanity a thousand times that amount."

GASTROJEJUNOSTOMY IN GASTRIC AND DUODENAL SURGERY

There has been for some time a considerable amount of discussion and differences of opinion as to the relative merits of the methods of surgical treatment of gastric and duodenal ulcers. Some surgeons advocate radical operations for these forms of disease and other surgeons pin their faith to less severe operative procedures, while all seem to be agreed, surgeons at any rate, that in chronic serious cases of these disorders, the best hope for recovery lies in surgery. Of the well known surgeons who have had extensive experience in the treatment of these ulcers, Mr. Herbert J. Paterson, senior surgeon of the London Temperance Hospital, has adhered always to gastrojejunostomy for the cure or relief

of these conditions. At the recent meeting of the British Medical Association he read a paper on the subject, in which he reviews the situation thoroughly and states that in his opinion it is time that a stand be made against operations which are unnecessarily severe, and he contends that in the great majority of cases gastrojejunostomy is a thoroughly satisfactory treatment both for gastric and duodenal ulcers provided it is performed properly and that prolonged and efficient aftertreatment is carried out.

He holds that the claims made for partial gastrectomy, that it is a more certain cure, will not bear a close analysis. The mortality rate is higher than that of jejunostomy and although in the hands of a few experts the death rate from it does not much exceed the death rate of gastrojejunostomy few will be prepared to deny that it is a more severe operation with a necessarily higher mortality.

Paterson combats strongly the allegation that some sixty per cent. of chronic ulcers show malignant changes, which is one of the strongest reasons advanced for their complete removal. He is inclined rather to attribute the occurrence of gastric ulcer to intestinal stasis rather than to gastric ulcer. He argues that if it be true that sixty to seventy per cent. of chronic ulcers are, or become malignant, then it follows that often gastrojejunostomy must be performed for ulcers which are believed to be innocent but which are really malignant. Consequently a large number of these patients should die subsequently from gastric cancer. It is known, however, that this is not the case. Statistics say that the proportion of those who die from carcinoma after gastrojejunostomy for supposed simple ulcer is about two per cent. The most conclusive evidence against the supposition that gastric ulcer is frequently of a cancerous nature is that patients seldom die from gastric cancer after gastrojejunostomy for a presumably simple ulcer. Therefore, the logical deduction is either that the ulcers are rarely malignant or that gastrojejunostomy cures them. Therefore those who claim that gastric ulcers become frequently cancerous are on the horns of a dilemma.

Figures are quoted showing the results of Paterson's gastrojejunostomy operations from 1913 to 1923. These are most satisfactory.

So far as gastric ulcers are concerned, the author insists that gastrojejunostomy is the operation of choice for all cases of gastric ulcer except those in which there is a more or less strong suspicion that the ulcer is cancerous. And with regard to duodenal ulcers, Paterson states that there is no question that success can be attained by gastrojejunostomy in over ninety per cent. of the cases of duodenal ulcer, and consequently duodenectomy is a totally unnecessary operation.

The contraindications to gastrojejunostomy are that it should never be performed except when there exists an ulcer which can be seen and felt. It should never be done on a clinical diagnosis, however clear and definite the symptoms, and lastly, it should be borne in mind that gastrojejunostomy will not cure tabes dorsalis, migraine, gallstones or cancer of the intestine. Neither will the operation give good results if a gallstone or a diseased appendix be left in the abdomen. The importance of after care of the operation is emphasized.

Paterson twits Sir Berkeley Moynihan, the great advocate of gastrectomy, with his change of view. Not long ago Moynihan extolled gastrojejunostomy in glowing terms and Paterson quotes his words to this effect. He bases his belief in gastrojejunostomy mainly because it is a physiological procedure and because by his success with it he has proved it to be so. The paper is highly informative and deserves to be read closely by the medical profession.

PHYSICAL AND MENTAL HEALTH

"She suffered from bodily weakness the greater part of her life and but for an extraordinary mental health—inherited from the fine yeoman stock from which she sprang—it is impossible that she could have retained, at all times, so sane a view of human conduct or been the least sentimental among women writers of the first rank—the one wholly without morbidity in any disguise." So writes a biographer of George Eliot, and it is worth while to pause over this statement in a period when many of us are in the custom of ringing the changes on that old Greek phrase—a sound mind in a sound body, as if only physical athletes and only persons with sound livers or lights could produce great works in literature or art.

George Eliot suffered severe headaches of we know not what origin, though some modern clinician would point to a misbehaving pituitary as the source of the disturbance. Possibly, also, he would be silly enough to go more afield and attribute her genius in literature to the undue activity of this same gland or one of its colleagues of the endocrine series.

As for livers and lights, some of the most brilliant feats of genius have been conceived and executed with men in the last stages of consumption or of hepatitis, and, though it is astonishing that the brain should have functioned so marvellously under the circumstances, such has been the case. Possibly these seers saw deeper for their nearness to eternity, and yet very great works have been produced by the healthy and robust in the height of health, as exemplified in poetry by Robert Browning, in painting by Sargent, in music by Brahms.

Nevertheless there is some relationship between

good health and good mentality. As Karl Pearson says, "While health and intelligence are not highly correlated," and while "Nature selects for physique and she selects for intelligence . . . where the physical machine is not of the highest order, there the mental machine will, on the average, run less smoothly, although by no means in complete accord."

If George Eliot had prostrating headaches, she was far from being physically weak. D. H. Banner, in an article on Sargent in the *Nineteenth Century,* would have us believe that "where actual weakness exists no greatness is possible." "Few realize," he continues, "how immense is the effort demanded by artistic creation." The daily effort put forth by a genius of the first distinction "is of a kind and of a degree which an ordinary man (even if he could be imagined to make it at all) would only make it at the cost of his life. It would shatter his body and burst his brain. Men have spoken of the delicacy of Chopin and (save the mark!) of Keats: they did die young, but they were strong in body and mind far beyond the common order—they could not, otherwise, have been artists of the first rank, as they are."

Mental disease and mental mediocrity may exist with good health and fine physique. Healthy and finely working minds may exist in sickly and frail bodies, but, on the whole, the greatest and best mental productivity is associated with good physique and harmonious behaviour of all working parts.

DIETETIC TREATMENT OF GASTRIC ULCER

It is superfluous to emphasize the point that in the medical treatment of gastric ulcer diet is of supreme importance. Dr. Arthur F. Hurst in the *Textbook of the Practice of Medicine,* edited by Dr. Frederick W. Price, stresses the fact that the object of treatment of gastric ulcer is to reduce the secretion of gastric juice as much as possible, and to keep the hydrochloric acid in the stomach completely neutralized throughout the day, and, what is almost invariably neglected, throughout the night. The evidence is conclusive that free hydrochloric acid prevents an ulcer from healing. At the same time as much food as possible is required to maintain the patient's nutrition. Finally, the food should be non-irritating in its mechanical and chemical character.

In the *Boston Medical and Surgical Journal* for April 22, 1926, Dr. A. Everett Austin reviews the progress of gastroenterology in 1925 and refers to the dietetic treatment of gastric ulcer. As an outcome of investigations undertaken to determine the ingestion of fat and starch, the digestion of cheese and bread and the digestion of fresh and stale bread by the healthy stomach or the stomach diseased with old ulcers, concluded as follows: 1, That fat mixed thoroughly with starch is better borne than alone; 2, that the coarse starchy foods are better fitted for digestion when mixed with fat; 3, that cheese is better digested when taken with bread; and 4, that old bread gives less secretion of hydrochloric acid than fresh bread.

Jarotsky in seeking to provide a diet which will pass through the stomach without delay and without exciting gastric secretion, recommends the following: white of egg, because it is semifluid and has no extractives, and unsalted butter, because the fat tends to suppress gastric secretion and has great nutritive value. He insists that these should not be given together but at alternate periods. Two restrictions must be observed in the employment of this diet. No water must be taken by the mouth or rectum and sodium citrate must be avoided. It is asserted that even gastric hemorrhage does not militate against the use of this diet, as patients do better than on rectal feeding. Systematized, this diet calls for, on the first day, the white of one egg in the morning and at 3 p. m. twenty grams of fresh butter. Each day the white of egg is doubled in quantity, as is also the twenty grams of butter, so that on the tenth day the patient is getting ten eggs and one hundred and eighty grams of butter. Marked pyloric stenosis is the only contraindication to not continuing this diet for ten days. After ten days the patient may begin to take gruels of rice, tapioca, etc.; with an abundant supply of unsalted butter, mashed or baked potato. No milk is to be given during the whole treatment.

Hurst gives both milk and sodium citrate while the milk may be flavored with tea, coffee or cocoa and in cases requiring prolonged treatment the monotony of the diet can be relieved by the substitution of an equal quantity of custard, junket or arrowroot to which apple or red currant jelly may be added for some of the feeds and potato artichoke or other vegetable purée for others. Immediately before alternate feeds beginning at 7 a. m., half an ounce of olive oil is taken. This inhibits the secretion of gastric juice and supplies a digestible and unirritating food in concentrated form.

Strict dietetic treatment should be continued until for three weeks the patient has had no spontaneous pain, no trace of tenderness has been present, no occult blood has been found in the stools and the x rays no longer show the presence of an ulcer crater. The diet can now be rapidly increased until at the end of a week everything may be taken with exceptions enumerated by the author.

Hurst points out that it is not difficult to cause an ulcer to heal by suitable treatment in bed, but the predisposing exciting cause may still be present. Special precautions are therefore required to prevent recurrence. The patient should eat slowly and masticate

thoroughly. It is better to drink milk and eat a chocolate bar in the middle of the day than to bolt some less digestible solid food. Tough meat, new bread and other articles of food which cannot be chewed to a fluid consistence should be prohibited. Among other things prohibited are salads and all uncooked vegetables. The patient should remain strictly on a régime until he has been free from symptoms for two years, and should follow it in a modified form for the rest of his life.

As said before, the object of treatment is to keep the secretion of gastric juice at a minimum and to keep the hydrochloric acid in the stomach neutralized by day and night. Diet plays a predominant rôle in the accomplishment of this end and it is the aim of treatment to find a diet which fulfills the aforestated object of treatment. It is somewhat curious to note that authorities such as Hurst and Jarotsky do not agree in the value of milk and sodium citrate in the early treatment of gastric ulcer.

THE SCIENCE OF SANITATION

The opening session of the Jubilee Congress of the British Sanitary Institute took place on July 5, 1926, at Guildhall, London. Mr. Neville Chamberlain, Minister of Health, gave the presidential address. He pointed out that it was a remarkable reflection that the period of time during which the institute had been in existence had seen the development of the science of sanitation taken at a bound out of the Middle Ages into its present condition. In the year 1875, he said, the gross expenditure from revenue and from loans from local authorities in England and Wales on public health services appeared to have been just over £5,000,000; in 1923-4 the figure was over £61,000,000, and in addition over £27,000,000 was spent on housing in that year.

As regarded personal hygiene, one of the chief needs of the moment was more adequately to coordinate the existing services. The scheme of poor law reform which he had circulated for consideration had such coordination as one of its main objects. He hoped that there would be means of bringing the work of the great voluntary hospitals into closer relation with the health work which was being done by public bodies. He had been thought on a previous occasion to foreshadow a scheme under which the voluntary hospitals would be brought under public control. That was not his wish. His own strong conviction was that it would be a misfortune if they lost their present voluntary character. His hope was that, while retaining this character to the full, they would be able to cooperate more closely in the general campaign which the community, through public and voluntary institutions, was conducting for the conquest of disease.

The fight against chronic disease in Great Britain is being pursued with vigor, but, as Mr. Chamberlain pointed out, combined and coordinated efforts are needed to effect the best results. In the prevention of disease, unless the public take an active and intelligent part, the outcome will be unsatisfactory. But to take such a part, its members, and especially its women members, must be educated in the methods and practice of personal and domestic hygiene, and the manifest rôle of the doctor is that of educator.

Obituary.

JOHN THOMSON, M.D., LL.D., F.R.C.P.

Edinburgh

One of the greatest authorities on children's diseases, Dr. John Thomson, died at his home in Edinburgh on July 2, 1926. He was the son of Thomas Thomson, writer to the Signet, and was born in Edinburgh in 1856. He was educated at Edinburgh Academy and University and did postgraduate work in Vienna and Berlin. In Berlin he worked under Professor Henoch, the great German pediatrist, and developed a natural bent to the study and practice of diseases of children. For longer than forty years he practised in this branch of medicine with unflagging zest so broadening his knowledge that he became one of the best known specialists in the world.

In 1889 he translated Henoch's *Diseases of Children* and in the same year was appointed assistant physician to the Edinburgh Hospital for Sick Children. He published in 1898 *The Clinical Study and Treatment of Sick Children,* one of the best practical books in print. He was essentially accurate and thorough in all he did or wrote. His writing was based on the acid test of experience. Thomson upheld the value of clinical experience in the face of the onrush of bacteriology and biochemistry which threatened to obscure its importance. Like his friend the late Sir James Mackenzie, he deplored the fact that teachers and practitioners obsessed with the glamor of bacteriology and biochemistry were inclined to belittle practical experience and to lean too much on the result of laboratory findings. Both of these men were earnest and persistent searchers after truth. Thomson excelled as a bedside teacher, and it was a liberal education in the art of diagnosis to accompany him through the wards and in the outpatient department.

He assisted to found the Edinburgh Cripple Children's Aid Society and gave much of his time to the study and treatment of mentally defective children. Indeed his work on mental deficiency had a great deal to do with attention being directed to its importance. He aroused interest in a subject which had been neglected, an interest which continues. The literary work of his life was his great textbook of children's diseases, a new edition of which he had completed shortly before his death. Personally no man in the medical profession was more respected and loved than John Thomson. He represented the best type of Christian and was in every respect the unassuming gentleman with that strain of simplicity in his "make up" not infrequently seen in great men.

The Hollywood Hospital

EARL M. TARR, M.D.
Los Angeles, Calif.

In reading the first two paragraphs of the first Annual Report of the Hollywood Hospital one learns that:

"February 20, 1920, found Edward Hawkins, a young English promoter, a very sick man in a room at the Hollywood Hotel. The house doctor, Sharon M. Atkins, was unable to find for him an empty bed in a hospital in Los Angeles. After much telephoning, a local cottage insane asylum graciously admitted the patient. Mr. Hawkins recovered.

"Los Angeles, with one million population, had but one and one half beds per thousand; Hollywood, with a population of one hundred thousand, had none at all, and her fifty-nine regular physicians and an unusually discriminating people were entirely dependent on the mother city for hospital beds in time of trouble. Five beds per thousand were conceded to be but safe hospitalization under ordinary conditions."

The only unusual thing about this situation was that, upon recovery, Mr. Hawkins was allowed to leave the insane asylum without being required to prove that he was of sound mind.

A group of public spirited people took it upon themselves to plan a hospital for Hollywood. The Hollywood Hospital Company was formed and a lot was donated for hospital purposes. The City Council promptly refused a permit to use this lot for a hospital. The present location (in the same block with the Children's Hospital, a Class A institution) was then decided upon. Unscrupulous politicians again did all in their power to block the hospital plans. Fortunately, the City Council looked upon the present location with favor and passed the ordinance. The Mayor of the city (who had been generously supported by the Medical Profession) vetoed the measure. The matter was passsed over his head and a recall petition settled the political difficulties. Disgraceful as the whole affair was, it undoubtedly gained for the hospital many loyal friends.

Plans were then completed, contracts let, and actual construction began February 10, 1923. The first patient was admitted on May 15, 1924. Before the day was over there were fifteen patients admitted, three infants had been born and several accident cases were treated. So much for the beginning of Hollywood's first hospital.

The capacity of the hospital at present is one hundred fifty. Plans for additional wings have been made and construction of the next unit will probably take place very shortly. It is most gratifying to know that the hospital has been approved both by the American College of Surgeons and the American Medical Association.

The cost of the service in this hospital (four dollars and a half to six dollars for ward beds—six dollars to fifteen dollars for private rooms), at first glance, appears to be rather high.

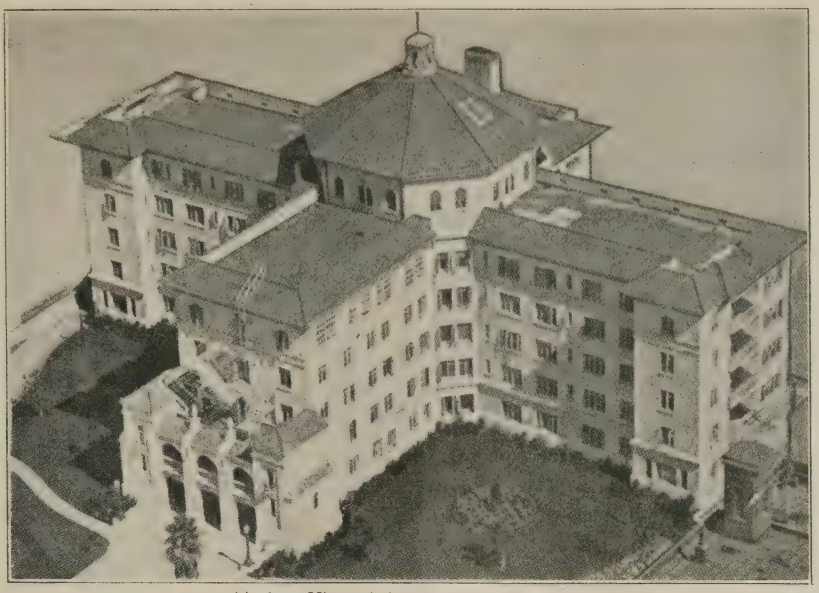
But when it is considered that many of the usual extras have been eliminated and that only graduate nurses are employed, it will be found that the cost compares favorably with that of other first class hospitals in the city.

On the active staff are some of the best doctors in the city, in this respect being normal. The management of the hospital is in the hands of a general superintendent who, because he is a medical man and because of his vast experience and executive ability, has his fingers on the pulse of the entire institution at all times. The hospital owes much to him for its steady and rapid growth as well as for its most efficient management.

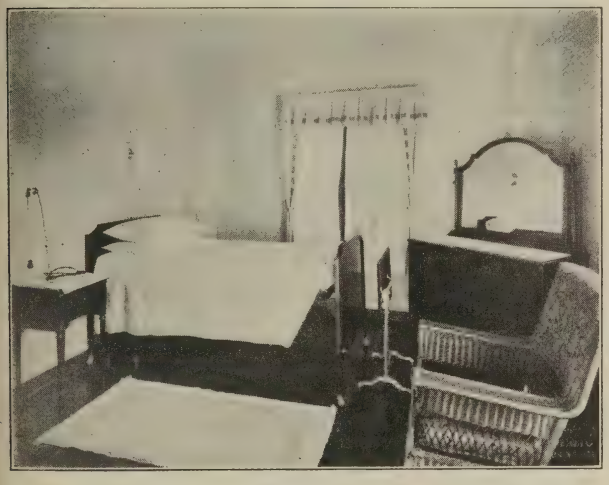
The need for such a hospital is well shown in the report for the first six months. Over two thousand cases were admitted and the average number of patients in the hospital per day was 109.1. One thousand four hundred and ninety-six operations were performed and four hundred and seventy-eight babies were born. The death rate was 32.5 per thousand, which is about 2.5 per thousand below the hospital average. These results have been attained in spite of the difficulties of opening and organizing a new hospital.

The executive organization of the hospital consists of the board of directors, officers of the hospital and the several advisory committees. President of the board of directors, Dr. Edwin O. Palmer; medical executive, Dr. Walter E. Deering, chairman; general superintendent, Dr. T. R. Ponton; chairman of the staff, Dr. Lucius J. Huff; secretary, Dr. T. R. Ponton.

The six advisory committees meet with the officers of the hospital at regular intervals and discuss ways and means of improving the service and standing of the institution. Medical advisory committee, Dr. Lucius J.

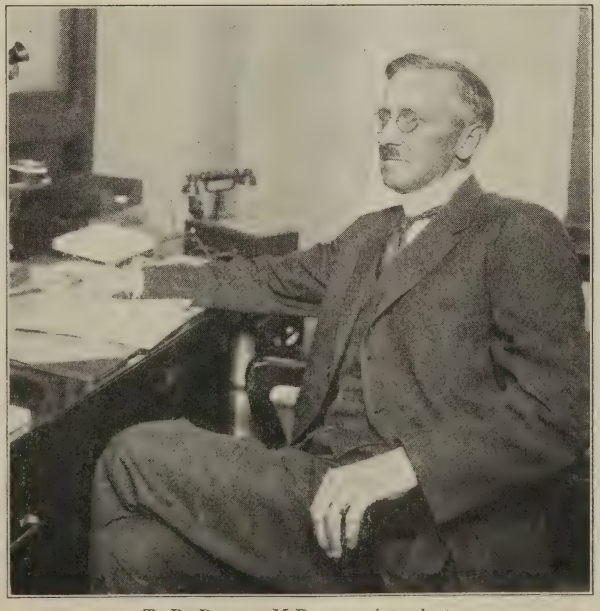


Airplane View of the Hollywood Hospital.



Private Room.

A Corner of the Modern Hospital Kitchen.



T. R. Ponton, M.D., superintendent.

Huff, chairman; surgical, Dr. Foster K. Collins, chairman; medical, Dr. Paul B. Roen, chairman; orthopedic and pediatric, Dr. Earl M. Tarr, chairman; obstetrical, Dr. Walter E. Deering, chairman; eye, ear, nose and throat, Dr. Theodore C. Lyster, chairman.

In the average hospital one nurse is supplied for four patients. In the Hollywood Hospital the proportion is one nurse to three patients. Graduate nurses are employed, and because of the excellent arrangement of the utilities, each nurse is able to give a maximum of time to the care of patients. Special nurses are unnecessary except in cases of extreme illness.

Staff meetings are held once each month. Subjects of medical interest are discussed and most original contributions appear later in first class medical journals. Problems of research are being carried on and many preliminary reports have been read before the general staff. Plans for the publishing of a *Staff Bulletin* are under way.

2007 Wilshire Boulevard.

News Items.

Ithaca Adds Hospital Wing.—A communicable disease ward with a twenty-two bed capacity has recently been completed at the Ithaca General Hospital. The new wing contains three stories and was built and equipped at a cost of $90,000.

Public Health Service Entrance Examinations.—Examinations of candidates for entrance into the Regular Corps of the U. S. Public Health Service will be held, on October 4, 1926, at the following named places on the date specified: Washington, D. C., Chicago, Ill., New Orleans, La., and San Francisco, Cal.

New Bronx Hospital Cornerstone Laid.—Mayor Walker officiated at the recent laying of the cornerstone of the New Bronx General Hospital at the corner of 168th Street and Gerard and Walton Avenues, the Bronx. When completed early next year, the hospital will have four hundred beds and will be under the administration of the New York City Department of Public Welfare.

Minnesota Society of Internal Medicine.—This society was organized on June 11th at a meeting of the St. Paul Town and Country Club. The first officers elected were Dr. Charles Lyman Greene, president; Dr. George D. Head, vice-president, and Dr. Edwin L. Gardner, secretary-treasurer. The first scientific meeting of the new organization will be held at Rochester in November.

Pharmaceutical Research.—The National Conference on Pharmaceutical Research will hold its fifth annual meeting at the Bellevue-Stratford Hotel, Philadelphia, on Saturday, September 11th. Delegates from the fourteen affiliated organizations will be present and present reports. The general discussions will be on census of research, graduate students in pharmacy and their research work, research topics, research grants and prizes, and research fellowships and scholarships.

International Postgraduate Medical Courses in Berlin.—Announcement is made that postgraduate-medical courses, international in scope, will be held in Berlin, October 4th-30th, under the joint auspices of the medical faculty of the University of Berlin, Kaiserin Friederick-Haus, and the assembly of academic lecturers. The courses have been arranged as follows:

October 4th to 16th, general medicine, with special attention to the latest advances in therapeutics.

October 18th to 30th, urology.

October 4th to October 30th and October 4th to October 18th (two separate courses), special departments of all branches of medicine.

Further information may be obtained from Kaiserin Friederick-Haus, Berlin, NW6, Luiseplatz, 2-4.

Portrait of the Doctors Mayo.—Gerald Cassidy, the artist, has recently painted portraits of Dr. William J. and Dr. Charles H. Mayo, which will be hung in the new clinic building to be completed in the near future at Rochester, Minn.

Preliminary Program of Tuberculosis Meeting.—The preliminary program of the twenty-second annual meeting of the National Tuberculosis Association, to be held at the Mayflower Hotel, Washington, D. C., October 4-7, is published in full in the June issue of the association's *Bulletin.*

Coming Conventions.—Meetings to be held during September and October include the International Union Against Tuberculosis, Washington, D. C., September 30th-October 2nd; National Tuberculosis Association, Washington, D. C., October 4th-7th; Conference of Health Officers and Public Health Nurses, Buffalo, N. Y., October 12th.

Metropolitan and Manhattan Hospital Merger.—Supreme Court Justice Mahoney of New York signed an order on July 21st permitting the consolidation of the Metropolitan Throat Hospital of 351 West Thirty-Fourth Street with the Manhattan Eye, Ear and Throat Hospital of 210 East Sixty-Fourth Street under the name of the latter.

New Cancer Laboratory—A modern cancer research laboratory will be opened in the near future by the Scientific Committee of the recently organized New York Cancer Association. The top floor of an eight story building at 250 West Forty-Ninth Street, New York, has been leased for the laboratory and plans have been drawn under the supervision of Dr. Isaac Levine, director of the association. The cost of improvements will be $75,000. A budget of $108,000 for the first year has been planned. The laboratories will have 7,500 square feet of floor space. There will be a lecture room with a seating capacity of 150, a publication office, a laboratory for the scientific director, and separate laboratories for physical chemistry, biology, radium, bacteriology, high voltage x ray therapeutics, experimental physics, organic and inorganic chemistry. There will be a staff of about thirty-six, including twelve research workers besides the technical assistants. The Scientific Committee in charge of the undertaking includes, in addition to Dr. Stewart, Dr. Barnet Joseph, representing the New York City Cancer Institute; Dr. Samuel A. Brown, dean of the Medical School of New York University; Dr. Holmes C. Jackson, dean of the Dental College of New York University; Dr. Alfred T. Osgood, professor of surgery at New York University; and Dr. William H. Park, director of laboratories of the Department of Public Health of New York City.

Personal.—Dr. J. N. Sandblom, dental surgeon to the King and Queen and Royal Court of Sweden was a recent visitor in New York City. He was suffering from toothache upon his arrival.

Dr. Simon M. Jacobs of New York and his family have been spending some time abroad for purposes of study and pleasure.

Announcement has been made of the marriage of Dr. Louis A. Friedman and Miss Della Weintraub.

Dr. Isidor J. Landsman, who has been connected with the x ray department of Fordham Hospital, New York City, for several years, has been appointed röntgenologist at Bellevue Hospital.

Dr. W. D. Coolidge, assistant director of the research laboratory of the General Electric Company and inventor of the x ray tube which bears his name, has been awarded the Howard N. Potts gold medal for 1926 by the Franklin Institute of Philadelphia. The medal, to be formally presented on October 20th, is "in consideration of the originality and ingenuity shown in the development of a vacuum tube that has simplified and revolutionized the production of x rays." In accepting the medal, Dr. Coolidge will present a paper on his new and powerful cathode ray tube.

Among members of the American Gynecological Association who have recently sailed from New York to visit European clinics and hospitals are Dr. J. Wesley Bovee, Dr. Joseph Brettauer, Dr. William E. Caldwell, Dr. Frederick C. Holden, Dr. George V. Kosmak, Dr. Franklin H. Martin, Dr. C. Joff Miller, Dr. Reuben Peterson, Dr. J. O. Polak, Dr. Richard R. Smith, Dr. Howard C. Taylor, and Dr. George Gray Ward.

Book Reviews

DIGESTIVE DISTURBANCES

Modern Views on Digestion and Gastric Disease. By Hugh MacLean, M.D. New York: Paul B. Hoeber, Inc., 1926.

MacLean's book on digestive disturbances is of great interest. It shows a tendency to return to views held formerly by pioneers in gastroenterology (Riegel, Ewald, Boas, Leube). The author's opinion that the degree of acidity of the gastric contents is usually due to a reflux of duodenal contents (pancreatic juice and bile) into the stomach and that this forms a normal process, cannot be accepted as a fact. MacLean's description of nervous dyspepsia is very practical. He says:

Nervous dyspepsia is one of the bugbears of the clinician. Though many cases can be diagnosed with ease, it is sometimes exceedingly difficult to be certain whether or not an organic lesion is present, and the most experienced observers frequently make mistakes. The condition may simulate, in every particular, some other gastric disease, such as ulcer, and the greatest care has to be exercised in dealing with these cases. The symptoms complained of are usually flatulence and abdominal discomfort, which sometimes, though not often, amounts to definite pain; occasionally, complaints of very severe pain are made. Bad taste in the mouth and loss of appetite are common, while vomiting is sometimes present. In short, the symptoms are such that frequently they would fit in with any diagnosis as far as gastric ailments are concerned. Though vomiting is not very common, I have seen a patient who vomited regularly for two and a half years after every meal. A hint as to the cause of the dyspepsia may be obtained from a consideration of the fact that the symptoms often vary from hour to hour and day to day, without any apparent reason. As a rule, they bear no definite relation to meals. This nervous dyspepsia is very common in hysterical and neurasthenic subjects, and as it is well known that the neurasthenic nearly always feels worse in the morning and better as the evening advances, it is always suspicious of a nervous origin when the gastric symptoms tend to improve towards night. General symptoms, such as headache, tiredness, depression, various pains in different parts of the body, and constipation, are often present. Frequently the patient is exceedingly introspective. Definite tenderness may be elicited in the upper abdominal region. It must be emphasized that in cases of this type the whole of the circumstances must be carefully considered in arriving at a diagnosis.

With regard to the etiology of cancer, we know practically nothing. Cancer is frequently supposed to follow a chronic gastric ulcer, the idea being that the ulcer undergoes malignant changes. On this assumption many textbooks make the statement that the majority of cases of cancer arise in patients who have had a long history of chronic dyspepsia; that the symptoms of this dyspepsia undergo a change at some period, and that this change marks the onset of malignant degeneration. How such statements ever came to be made is a matter for wonder, for careful examination of cancer patients shows definitely that this story is but a figment of the imagination. Certainly, on the assumption that ulcer precedes cancer, patients suffering from cancer ought to give evidence of a long history of chronic gastric ulcer. That they most assuredly do not, save in exceptional cases, is one other instance in which theory is shattered by fact.

More than twenty years ago the author set out, on the basis of the current teaching, to ascertain as nearly as possible what percentage of patients suffering from cancer had previously had definite dyspeptic symptoms which might be attributed to ulcer. To his intense surprise, no evidence of previous gastric disturbance was forthcoming in the great majority of cases, and ultimately the conclusion was forced upon him that cancer is really an acute disease which usually arises *de novo,* and not, as a rule, in a patient suffering from previous ulcer. Since that time further examination of the problem has amply substantiated this impression. The "ulcer-cancer" bogey is one of the mysteries of modern medicine. The question can be so easily settled, and yet, in spite of overwhelming evidence to the contrary, which can be seen by anyone who comes in contact with cancer cases, many clinicians place implicit belief in the view that the chief factor in the etiology of cancer is chronic ulcer.

The records of any hospital will conclusively prove that cancer is not usually associated with previous dyspepsia of long duration, and that, in nearly all the cases, the symptoms existed only for a short time before the examination.

The present volume is very practical and can be recommended as a useful addition to the practitioner's library.

Diätetik der Magen- und Darmkrankheiten. Von Prof. Dr. I. Boas. Zweite Auflage. Leipzig: Geo. Thieme, 1926.

The second edition of Professor Boas's book on diet in digestive disorders appears now in the form of lectures. This is a great advantage to the reader, as the conversational form is more enjoyable and easier understood. The author stresses the importance of abundant nutrition, especially in all cases of subnutrition. He also deprecates the too frequent use of broths, gruels and mashed vegetables to the exclusion of ordinary foods—when there is no indication for such a procedure. In peptic ulcers Boas does not favor the Lehnhartz diet (milk, eggs, and meat), as this interferes with the stool examination for blood. Nor does he recommend the Sippy régime, on account of the danger of alkalosis.

In the treatment of constipation Boas is a great advocate of olive oil and liquid petrolatum in conjunction with a diet containing plenty of vegetables, salads and fruits. In diarrheal conditions (chronic enteritis) fruits, salads and milk are not given, nor ice cold beverages. In some instances a fast of two days is advocated, before instituting a dietary régime.

A special feature of the book is formed by Kelling's lectures on diet after operations on the gastrointestinal tract.

This book on diet by Professor Boas, who is the greatest living master on gastroenterology, abounds

in excellent good advice in the management of the digestive diseases. It should find a prominent place in every physician's library.

Leçons de Pathologie Digestive. Par Professeur M. Loeper. Paris: Masson et Cie., 1925.

Professor Loeper's lectures on digestive disturbances are of great interest. There is a special chapter on syphilis of the stomach, the importance of which is well known. Another chapter deals with dyspepsia and erythremia, or polycythemia or Vaquet's disease. The most various dyspeptic states are encountered in combination with polycythemia. Thus fulness after meals and flatulence; pains late after meals simulating duodenal ulcer or pylorospasm; sometimes hyperchlorhydria and constipation; at times dizziness and nausea; sometimes gastric or intestinal hemorrhages.

The treatment in all these dyspeptic conditions must be directed, not so much against the form of dyspepsia present, as against the polycythemia which caused the dyspepsia. The principal indications are: bleeding; washing of the blood; diminishing its viscosity. The bleeding can be done by scarifications or best by venesection. The washing of the blood by drinking plenty of water between meals, or by rectal injections of saline by the Murphy drip. To diminish the viscosity of the blood there is no better remedy than citrate of magnesia, of which three to six grams daily should be administered.

This excellent book is herewith warmly recommended.

LACTOBACILLUS ACIDOPHILUS

Lactobacillus Acidophilus. By Nicholas Kopeloff, Ph. D. Baltimore: The Williams and Wilkins Company, 1926. Pp. 211.

This is a careful and painstaking piece of work. Written by a bacteriologist, it brings to the practising physician some of the spirit of rigid technic and straight thinking of the sister sciences.

The style is very clear. The data on which conclusions are based are given in full. Not only are the bacteriological aspects thoroughly covered, but the chemical correlations are presented in a surprisingly complete and convincing manner.

The book is not faddist and should therefore be all the more useful in an era where new medicaments are exploited in none too scientific a manner.

PHYSIOLOGY FOR STUDENTS

A Textbook of Physiology. By William D. Zoethout, Ph.D., 2nd Ed. The C. V. Mosby Company, St. Louis. Price, $4.50.

As stated in the preface, the aim of the book is to give dental, pharmacy and normal school pupils with limited time as short and comprehensive a course in physiology as possible. To this end, as the author indicated, the book develops the practical side of nutrition, physical exercise, mental work, fatigue and kindred topics.

Recently where dental schools have become amalgamated with medical schools the study of physiology is much more thorough, and the students would not be allowed to pass with only a smattering of the subject as is inevitable with this work.

MALIGNANCY AND EVOLUTION

Malignancy and Evolution. A Biological Inquiry into the Nature and Causes of Cancer. By Morley Roberts. London: Eveleigh Nash and Grayson, Ltd., 1926. Pp. 307.

The literature on cancer is profuse, and has been especially so within the past twenty years. This arousing of interest in malignant disease is due to several causes, one of which is the popular propaganda on the subject intended rightly to inform the general public as to the early symptoms of the malady and to urge those who have or think that they have such symptoms to obtain expert advice and to secure, if necessary, the measures which are best calculated to prevent the disease from further development. The increase of cancer has also impelled earnest efforts of research in all civilized countries, mainly with the object of discovering the cause and these efforts have in turn given rise to a flood of literature.

A few laymen have contributed their views upon the cause of this form of deviation from normal health. The latest of this band is Mr. Morley Roberts who has made a name as a writer of fiction and who is known as well as a poet and painter. It may be said, at once, that Mr. Roberts has equipped himself well for the task he has undertaken, that of a biological inquiry into the causes of cancer. He is deeply versed in modern biology but considers the question of cancer from the outlook also of a philosopher. His book would be remarkable if written by an investigator trained in the methods of scientific medical research from his youth upwards. As the output of a layman who did not begin to study biology until middle age it stands alone and appears likely thus to stand. However, Mr. Roberts denies that his lack of routine methods of laboratory research has hampered him in any way in his search for the truth concerning cancer, and avers that, on the contrary, it has aided him, in that he has been enabled to approach the subject with an open mind and in the attempt to unravel the mystery of cancer causation has not been led astray by preconceived ideas. His deep knowledge of sociology and psychology reinforced by that of biology together with his gift for presenting his views in coherent and logical sequence have combined to produce a work which is suggestive and fascinating.

The ruling motive of the book is to point out the striking analogies which exist between pathological conditions in animals and those in nations and societies, and he emphasizes the point that evolution and malignancy and all other diseases are as much matters of state as common social disorders, and he holds that if there were as many real men of science as there are men of law in legislatures this fact might soon be acknowledged. He compares nations and societies to human bodies, all of which are societies made up of units. In the case of the human body an immense society composed of minute units. It makes no difference, in the opinion of Mr. Roberts, what the size of these living units may be. Provided that they are grouped into societies the conduct of each individual of that society must be regulated by machinery devised for that purpose.

In a similar way Mr. Roberts insists that there must be machinery for regulating the conduct of the countless units of which the human body consists, and *pari passu* with the greater number of units and with

their more elaborate and more involved structure, the machinery of the body for the control of these units must be designed or evolved to meet these conditions. The government of the human body is sketched, the nervous system being recognized, of course, as the central directing power, and the parts played by the endocrines, by embryonic influence and so on are suggested. He leaves no source from which an analogy between human society and the human body can be traced untouched and concludes that the manner by which malignant tumors exhibit their characteristic feature, namely by invasion, is common to all living societies. He points out, however, that this invasion is not peculiar to malignant manifestations but is included in Nature's scheme of evolution, and he believes that pathological processes are normal in that they belong to the machinery of evolution.

Mr. Roberts is inclined to think that the pathologist takes too much upon himself in regarding pathology as the only true means whereby the cancer problem can be interpreted correctly, taking the view that malignancy is as much a biological and developmental problem as it is a pathological one. Also he has somewhat original ideas as to tumors. "After all," he says, "a tumor is merely a swelling and no more. When we speak of one that persists we have yet to class it. And the failure to class cancer lies at the root of the comparative indifference shown to it by nearly all scientific workers but those who regard it as an isolated problem and their special business."

A cancer then regarded from the author's consideration of the question from the biological, sociological and philosophical aspect, is a variation of the problem of growth. Its origin is that of the placenta and other growths. And the solution of the problem of cancer growth will be a long step toward solving the problem of socalled abnormal growths in the body.

The book now being discussed is the second one Mr. Roberts has written on medicoscientific subjects. In *Warfare in the Human Body* he brought forward his doctrine of "hostile symbiosis" which he suggested to proceed naturally from the laws of energetics, since the autonomy and resistance of parts are necessary if work of any kind is to be done in any possible mechanism, whether organic or inorganic. He proceeds in *Malignancy and Evolution* to apply the teaching of hostile symbiosis to the interpretation of abnormal growth and development with special reference to cancer and sarcoma. His entire argument is based on the contention that hostile symbiosis rules in all communities. Be civilization of the highest and be a community of the strictest law abiding tendencies interests are certain to clash sometimes and the only way out of the difficulty is to compromise. All units of society are hostile symbiotes to a greater or less extent. In the body, says Mr. Roberts, a like state of affairs exists. The living cell bears the same relationship to its living neighbors, one or other of which is ready to seize upon and take advantage of any weakness of its near dweller. And this being so, the explanation is suggested of the origin and development of malignant growths. If Mr. Roberts's theory of hostile symbiosis is accepted, this explanation is perfectly valid. If the directing forces of government of the body, as the endocrines, perhaps the thyroid in particular, the nervous system, and the substances termed by the author as endocrines, fail to break down a similar result ensues as when the stable government of a country fails. The cancer in the body acts in the same way as cancer in society. It is the outcome of the failure or breakdown of one or other of the directing forces.

Mr. Roberts deals with the causes to which malignant growths have been ascribed by various investigators, and criticizes their modes of research and conclusions reached, but space is lacking to discuss his views on this subject. Mr. Roberts takes a tilt against conditions of living in civilized countries and seems to infer that these conditions may be factors in the production of cancer. He points out that the great majority of mankind, especially in those countries which pride themselves on their manufactures, are deprived of pure air, of sunlight and natural food. Although this review exceeds considerably the limit allowed by the editor, the excuse must be that the book is so greatly out of the ordinary and the views expressed are so boldly original and stimulating. It is recommended warmly to medical readers.

BACTERIA

Pleomorphism in Bacterial Protoplasm, A Study in Psittacosis. By Andrew Todd McClintock. Privately printed. Archives of the Andrew Todd McClintock Memorial Foundation. Volume I.

In discussing remarks and conclusions of a scientist value is placed on the primary efforts when the work is successfully repeated in another laboratory.

Psittacosis is a comparatively rare disease, but readers of this book who work in laboratories will undoubtedly always be on the lookout for a couple of examples to study in the hope that some of McClintock's observations were correct.

Many questions occur that unfortunately cannot be verified from the original source. The technic seems not to have been good, since it appears that perhaps the green color often mentioned as the gram negative bacillus was pyocyaneus. If the single cell isolations had been used there would have been eliminated the possibility of overgrowth of anaerobes and other bacteria by pyocyaneus. Even the pictures suggest mixed cultures.

The book is not clearly written and a good example of vague statements is the paragraph beginning Chapter X, on the hypothesis regarding disease of the animal organism.

The principle of the Foundation is most worthy and encouragement should be given to the production of carefully written and scientifically correct articles. After all, this book stimulates others at least to want to test the material even if only to obtain negative conclusions.

COLLECTED PAPERS

Collected Papers by the Staff of the Henry Ford Hospital (First Series, 1915-1925). With 151 Illustrations and 42 Charts. New York: Paul B. Hoeber, Inc., 1926.

These papers are all reprints of articles published in some of the leading medical journals of America. They indicate the highly scientific nature of the work done at the Henry Ford Hospital, but very many of them are of such a nature as to be of little practical value to the general practitioner. It is an excellent piece of bookmaking.

Medicoliterary Notes.

Dr. Huntington Williams, district state health officer of New York State, has an interesting article in the *American Journal of Public Health for August.* Another significant feature of this issue of the journal is a symposium on domestic and industrial wastes in relation to public water supply, including papers by Dr. John Emerson Monger, State director of health, Columbus, Ohio; George W. Fuller, consulting engineer, New York City; John H. Fertig, of the Pennsylvania Legislative Reference Bureau; and a report of the discussion of the problem in detail at the joint session of the Public Health Administration and Public Health Engineering Sections of the American Public Health Association at the American Health Congress held at Atlantic City in May.

* * *

Dr. Horace Carncross, psychoanalyst of Philadelphia, is the author of a forthcoming publication of Scribner's entitled *The Escape from the Primitive.*

* * *

Opportunities for Medical Women Interns is the title of an interesting article by Dr. Bertha Van Hoosen of Chicago in the July number of the *Medical Woman's Journal.*

* * *

The *World's Health* for May contains an excellent article by Raymond H. Torrey, on State Parks in the United States of America.

* * *

The *News Letter* for June, published by the National Committee for the Prevention of Blindness, contains a good reference list of articles in recent periodicals, both American and foreign, on ophthalmological subjects.

* * *

The New York State Department of Labor has made the August number of their *Industrial Hygiene Bulletin* a prevention of window cleaning accidents issue.

* * *

The *Monthly Bulletin* of the Philippine Health Service is running a series of interesting articles of Studies on the Serology of Leprosy. The initial article was in the September, 1925, issue of the *Bulletin.*

* * *

A patient in a Richmond, Va., hospital discovered recently, after undergoing an operation for appendicitis, that his appendix had been and that his liver was on his left side. He had known for some time that his heart was on his right side. He has enjoyed the best of health all his life, according to reports of the case.

* * *

The Biological Standardization of Insulin, including reports on the preparation of the international standard and the definition of the unit, is the subject of the latest report of the Health Oganization of the League of Nations.

* * *

The American Society for the Prevention of Cruelty to Animals, 50 Madison Avenue, New York City, is preparing for distribution reprints of a rare brochure, *Daggett's Rights of Animals,* of which a very small edition was published in 1791. The pamphlet was written as a thesis for a Master's degree at Brown University, Providence, in 1791. It was printed by David Frothingham at Sag Harbor in 1792 on heavy linen paper. The work had been considered lost for many years, until Edward P. Buffet of Stony Brook L. I., walked into the society's office with a photostat copy which he offered for publication.

* * *

The *State of Connecticut Health Bulletin* publishes in its June issue an informing article by Winifred W. Arrington, of the Division of Mental Hygiene, on Connecticut and the Mental Health Clinic.

* * *

The *World's Work* for July publishes a valuable contribution to the history of medicine in the form of an article by Sir George Newman entitled the Advance of Medical Science since 1876.

* * *

Chicago's Health for June contains a list of the larger cities of the world, exclusive of London and Osaka, with their death rates per 1,000 persons for 1925. These were, Chicago, 11.5; Berlin, 11.7; New York City, 12.2; Vienna, 12:9; Philadelphia, 13.2; Buenos Aires, 13.7; Paris, 14.7; Bombay, 25.4; Calcutta, 32.7.

* * *

In a recent contest conducted by the National Council for the Prevention of War votes were cast for twelve "world heroes" by the pupils of 195 American and 386 foreign schools. There were in all 609 candidates. The result was that Pasteur received the largest number of votes, with Lincoln second; the others chosen, in the order named, were Columbus, Washington, Franklin, Wilson, Florence Nightingale, Joan of Arc, Socrates, John Gutenberg, David Livingstone and George Stephenson.

* * *

The *American Mercury* for June contains an article by Clarence Darrow of Leopold-Loeb fame entitled The Eugenics Cult. It is chiefly a protest against what the writer feels to be an unwarranted invasion of our liberties and an unjustifiable attempt to interfere with the laws of nature. "We know something about biology," he writes. "We know a little about eugenics. We have no knowledge of what kind of man would be better than the one that Nature is involving to fit into the environment which he cannot escape. We have neither facts or theories to give us any evidence based on biology nor any other branch of science as to how we could breed intelligence, happiness or anything else that would improve the race. We have no idea of the meaning of the word 'improvement.' We can imagine no human organization that we could trust with the job, even if eugenists knew what should be done and the proper way to do it."

* * *

The July issue of the *Bulletin* of the Municipal Tuberculosis Sanitarium of Chicago is devoted to a full account of the recent tuberculosis survey of the city of Chicago made by the institution.

* * *

When the library of the famous Dutchman, Hermann Boerhaave, was sold at auction, a sealed volume bearing the title, *The Deeper Secrets of Medicine,* fetched one of the highest prices. When the seal was broken, the book was found to contain the following single sentence: "Keep your head cool and your feet warm; then you will defy all doctors."

* * *

A new publication which has recently made its appearance is the *Bulletin* of the Association of American Medical Colleges, with the July issue as its first number. Fifteen years ago the association published a quarterly bulletin, which, after a brief existence of two years, had to be discontinued because of lack of funds. Four years ago it was again decided that a bulletin should be published, but no funds were provided. The new bulletin is another endeavor to supply a long felt need for the dissemination of news of interest to medical colleges. It will be published quarterly by the Association of American Medical Colleges, 25 East Washington Street, Chicago, for free distribution.

* * *

Report has it that Rebecca West, young author of *The Judge* and other works, will come to America in the near future to make her home. Miss West has recently been in Italy with Miss G. B. Stern, the English novelist.

* * *

The Health Organization of the League of Nations has recently issued its third and final report on Cerebrospinal Meningitis in Prussia in 1923 and 1924, by Prof. Dr. E. Seligman of Berlin.

* * *

The National Library of London has obtained permission from D. Appleton and Company to transcribe *The Van Roon,* a novel by J. C. Snaith, into braille for the blind.

* * *

The *S. C. A. A. News* for July is a Cattaraugus County health demonstration number. Methods and exhibits are described in detail, with an account of the various meetings and other events of interest.

* * *

By a unanimous decision of the judges, the Indian play entitled *Nélagony, or Good Water,* submitted by the Pawhuska (Oklahoma) High School, was awarded the first prize of one hundred dollars in the national play contest offered by the National Tuberculosis. Anemone Pemberton is the author of the play. The songs and music are the work of the music department of the school.

Abstracts from Current Literature

GASTROENTEROLOGY

Celiac Disease: Its Definition and Diagnosis.—The following definition is suggested by Reginald Miller (*Lancet*, February 13, 1926): Celiac disease is a digestive disorder arising in infants and young children who show no evidence of chronic intestinal or other organic abdominal disease; it is characterized by a persistent malabsorption of dietetic fat, which causes large stools containing an excess of split fat, enlargement of the abdomen, lack of growth, and other symptoms.

DIFFERENTIAL DIAGNOSIS

The most characteristic diagnostic signs of celiac disease are as follows: 1, the abdomen is enlarged but shows no signs of organic disease; the buttocks are often peculiarly small; 2, except in severe cases in very young children, the abdominal wall is not conspicuously wasted; 3, with the same exception general wasting is not so severe as is the lack of growth—the weight for height is nearer the normal; 4, the excess of fat in the stools shows that fat wastage is out of proportion to that of other foods, and it persists when the rest of digestion is normal; 5, on a strictly low fat diet the amount of fat in the stools remains comparatively high, usually well over fifteen per cent. of the dried feces; 6, the fecal fat is invariably well split, the neutral fat being usually much below twenty-five per cent. of the fecal fat. The last three points display the essential features of celiac disease. There are two main types: the diarrheic (classical) and the nondiarrheic.

In the diarrheic type, the patient passes large, pale, unformed, and offensive stools containing a great excess of fat, chiefly in the form of fatty acid crystals, which from time to time may set up intestinal irritation with mucus in the stools. The diagnosis of this type may be discussed under various headings.

Rickets.—The catarrhal diarrhea of rickets is usually easily distinguished from the fatty diarrhea of celiac disease. In it the fat loss is neither so excessive nor so persistent. There is also the well known association between tetany and other spasmophilic signs in some cases of celiac disease, but taking the condition as a whole celiac children escape the grosser forms of rickets.

Tuberculosis.—Abdominal tuberculosis may produce fatty diarrhea in two ways: 1, by inflammation and ulceration of the intestine, and 2, by lacteal obstruction from tuberculous glands.

Chronic enteritis (enteric infantilism).—The difference between chronic enteritis and celiac disease is quite clear. In celiac disease there is first a failure of fat absorption with a secondary and transient intestinal catarrh. In chronic enteritis there is failure in the digestion of all sorts of foods, and the intestinal hurry and disease of the intestinal wall may cause an excess of fat in the stools. The therapeutic test in the two is different: the fat free diet in the one, and the low, easily digested diet in the other. In chronic enteritis the wasting of the patient is more severe than the lack of growth; the abdominal wall is usually thinned, and evidence of disease within may be felt, such as enlarged spleen or glands, or thickened intestine. The stools may be mucous and perhaps bloody; the digestion of all foodstuffs is impaired, that of the fat with, and not out of proportion to, the rest. As the enteritis subsides so fat digestion improves and does not persistently remain defective as in celiac disease. Finally, on a low fat diet the percentage of fat in the stools drops to a lower figure than in true celiac disease. In persistent enteritis a pancreatic steatorrhea, however, might develop; there may also be a distinct degree of stunted growth. The following types of chronic enteritis may give rise to difficulty in diagnosis: tuberculous enteritis, the dysenteric type, the Lamblia intestinalis type, the type due to irritant poisons and sprue.

Pancreatic steatorrhea.—The stool of pancreatic disease is large, pale, offensive, and oily. It contains a great excess of fat, and its diagnostic feature is the distribution of the fecal fat; a large proportion (over twenty-five per cent.) is in the form of neutral, unchanged fat, appearing in the stool, as separated oil or grease which congeals on cooling; in smaller amounts it appears microscopically as oil droplets. In celiac disease, on the other hand, the fat in the feces is well split. Pancreatic steatorrhea is rare in childhood. Congenital steatorrhea starts from birth and is almost certainly due to an inborn absence of pancreatic lipase, the other functions of the pancreas remaining unaffected. These patients show no stunted growth. Acquired pancreatic disease in children may occur as a sequel to chronic enteritis. It has also been attributed to inherited syphilis. Cases of pancreatic infantilism have also been reported.

Lacteal obstruction.—Fatty diarrhea is rarely caused by lacteal obstruction through the presence of tuberculous mesenteric glands.

In the nondiarrheic type the symptoms are all milder than in the classical diarrheic type. The chief difference between the two groups lies in the appearance of the stools. In the classical type with severe symptoms, the stools are large, pale, unformed, highly offensive, and containing forty to eighty per cent. of fat, chiefly in the form of fatty acids. In the nondiarrheic type the stools are again larger than normal, but they are colored, formed, not offensive, and contain thirty to fifty per cent. of fat, chiefly in the form of soaps. Similar stools are passed in the quiet stage of the diarrheic cases. Here the greatest difficulty arises in connection with two groups of cases: 1, temporary overfeeding with fat; 2, chronic enfeebled digestion of all foodstuffs.

Right Iliac Fossa Pain.—H. W. Carson (*Lancet*, February 13, 1926), confines his remarks to the less acute and to chronic conditions. He believes that acute conditions are much more certainly differentiated, and that even if operation is performed with a faulty diagnosis, the operation is probably essential and the real disorder is discovered and remedied. In chronic cases the outlook is very different, and if diagnosis is not very exact, and if the correct treatment is not instituted, not only is there a failure to cure, but the patient's sufferings may be aggravated.

Although it is twenty-five years since chronic inflammation of the appendix was first suggested as the cause of continued abdominal discomfort and ill health, the idea has become so firmly rooted that even today it is practically impossible for any one to avoid thinking of the appendix in every case where right iliac fossa pain is complained of.

One of the common causes of right iliac fossa pain is muscle strain, and it is seen in two classes of patients, the young schoolgirl and the middleaged athletic man who is giving up his sports and beginning to put on weight. The former strains her oblique muscles owing to vigorous exercise and the latter's pain is due to a commencing inguinal hernia.

A frequent cause of right iliac fossa pain is some trouble in the urinary tract. A stone in the ureter is, perhaps, the most likely to be overlooked. It is sometimes very difficult to differentiate roentgenographically between ureteric stone and tuberculous mesenteric glands without passing a ureteral bougie, not always a simple task in a child.

Tumors of the colon should be thought of. They may be tuberculous or cancerous. Both give rise, in addition to right iliac fossa pain, to a tumor which is in close relation with the anterior abdominal wall and are therefore easily detected; but cancer in the left colon often gives rise to right iliac fossa pain owing to back pressure and distention of the cecum when the growth itself cannot be felt. Pain in the right iliac fossa with a distended cecum in a constipated patient over fifty should always make one suspect a stricture in the left colon.

Then there are the cases of obscure etiology. The sufferers are generally women between the ages of twenty and forty. They are of spare build and have a characteristic carriage due to certain skeletal defects. The head is carried forward, there is a slight dorsal kyphosis, the ribs are close together and form an overacute angle with the rib cartilages, resulting in a flat, narrow chest with a reduced lower outlet. The lumbar concavity is abolished, and the sacrum articulates with the spine almost in a direct line instead of at an angle of thirty degrees. They complain of joint pains, neuralgia, headaches, and nausea. The abdominal wall is poorly developed and many points of tenderness are found in the abdomen, the right iliac fossa is especially sensitive, and often the secum is too easily palpable and the kidneys are frankly prolapsed. The stomach and large bowel are found

ptosed with delay in emptying. The appendix usually has been removed without relief. The cause of this right iliac fossa pain is posture, for it is relieved when the patient lies down. The two structures that are more mobile than they should be are the kidney and the right colon. Nephropexy has been abandoned in these cases because the kidney is only one among many displaced organs, and fixation of only one organ does not bring relief. The same may be said of the removal of socalled Jackson's membranes and fixation of the ascending colon.

But least of all has success attended the removal of the appendix in the socalled cases of chronic appendicitis. Here differential diagnosis is most important. Even though the appendix may show microscopic evidence of disease, appendectomy does not provide a clinical cure. Chronic appendicitis must not be diagnosed by right iliac fossa pain alone. The true symptoms of chronic appendicitis are those of the socalled appendix dyspepsia. The pain is felt in the epigastric or umbilical region, is excited by taking food—particularly some kinds of food—and is never relieved by recumbency. Nausea is very common. There is often an associated pain in the right iliac fossa, but this is never the only symptom. Nutrition is not impaired, nor is there anorexia, nor as a rule, constipation. This picture is in strong contrast to the other type where there is constipation, loss of appetite and energy, deficient nutrition, certain signs of nervous instability, and constant dragging pain in the right iliac fossa relieved by rest. These cases are often confused with gastric and particularly duodenal ulcer, or gallstones.

Röntgenography after a barium meal is of little value in diagnosing appendicitis. Radiologists are not agreed as to whether visualization of the appendix means that it is diseased, or whether failure to visualize the appendix means disease. Tenderness on pressure on the visualized appendix is open to misinterpretation as it overlooks the effect of pressure by a heavily leaded glove on the eleventh nerve. It has also been definitely proved that all ptosis is not pathological. With these reservations, roentgenography is of the greatest assistance in the diagnosis of the causes of right iliac fossa pain.

Pain confined to the right iliac fossa should not even be considered as due to appendicitis, especially in the absence of a previous attack, until the most painstaking investigation has disproved other possibilities.

Surgery of Stomach and Duodenum.—D. C. Balfour (*Surgery, Gynecology and Obstetrics*, Vol. XLII, No. 2) presents a report of four hundred cases of the more complicated lesions of the stomach and duodenum with an unusually low mortality. Some of the routine measures of operation as employed at the Mayo Clinic are given and the necessity of proper preoperative and postoperative care is strongly emphasized. Ethylene has been the general anesthetic, combined, when necessary with novocaine to produce block anesthesia, or sufficient ether to give satisfactory relaxation. Morphine one sixth grain and atropine one one hundred and fiftieth grain have been given as a routine half an hour before operation. The almost total absence of pulmonary morbidity and the low mortality in four hundred operations on the stomach and duodenum, one hundred and thirteen of which were for carcinoma, more than suggest the advantages of ethylene in these cases at least. The two disadvantages of ethylene are its inflammability and the difficulty of efficient administration. The former is not a menace if reasonable care is exercised, and the latter can be overcome by experience. Lundy has recently introduced into the Mayo Clinic. a combination of carbon dioxide with ethylene, which is more effective than ethylene alone.

There are certain points with regard to surgery of the stomach and duodenum which are always worthy of repetition. The first is adequate exposure, in which long incisions, usually in the left rectus, and selfretaining retractors and packs, are valuable aids. The second is adequate mobilization. This applies particularly to large gastric ulcers adherent posteriorly. It is frequently possible, by methodical mobilization of the stomach, to carry out satisfactorily, partial gastrectomy or excision, when the ulcer is situated so high that on first impression it appears to be irremovable. The third point is absolute hæmostasis. This can always be secured if scrupulous care is taken in the ligation of individual vessels and in the placing of sutures. The fourth point is the importance of avoiding incomplete operations, since a primary radical operation can often be performed with no more risk than an incomplete one, or one intended as the first of a two stage procedure. Another very useful adjunct is the suction pump. I have made it a routine to empty the stomach completely before finishing the operation, and often to empty and collapse the distended stomach with the pump before beginning the mobilization, as suggested by Devine. Finally there must be a proper appreciation of the mechanics of whatever operation is being performed; that is. the restoration of gastrointestinal continuity in such a way that adequate drainage is secured. Trauma should be kept at a minimum.

Diverticulitis and Its Surgical Treatment.—Diverticulitis is a condition of the latter half of life, due to the formation of small hernial protrusions from the lumen of the bowel through the muscular coat. These pouches or diverticula, may be found in any part of the alimentary canal (except possibly the rectum), but are most common in the large intestine and particularly in the pelvic portion.

J. P. Lockhart-Mummery (*Lancet*, February 27, 1926) states that we must recognize two distinct conditions due to pouching of the walls of the large gut. Diverticulosis, a condition in which there are numerous small pouches or hernial protrusions in the walls of the colon, which are demonstrable by examination with a barium enema under the x rays, but which is not accompanied by any symptoms referable to the diverticula.

The other condition is that of diverticulitis, in which secondary inflammatory changes have taken place in the diverticula, and definite symptoms attributable to these changes are complained of by the patient. Of the author's forty-one cases, twenty-five were in men and sixteen were in women. The average age was sixty, and the youngest patient was forty-two. It has been suggested that the cause of this condition is the habitual use of aperients, but the fact that the condition is commoner in men than in women seems to disprove this, as there can be no doubt that the habitual use of aperients is much commoner with women.

Vague pain in the abdomen, discomfort, slight disturbances of the bowel actions, are all too uncertain to be of much value, though, if they lead the doctor to have the colon examined by x rays, may reveal the condition. The typical symptoms of a developed diverticulitis are attacks of pain and tenderness over some portion of the colon, usually the sigmoid flexure, accompanied by a slight rise of temperature. Symptoms of chronic obstruction of the bowels accompanied sometimes by the presence of a palpable tumor, felt either through the abdominal wall or per rectum by bimanual examination, may present and will closely simulate carcinoma, but may be distinguished from it as a rule by the accompanying tenderness and signs of inflammation. The attacks may be at long intervals and there may be a history of difficulty with the bowels extending over a period of years. The diagnosis is often very difficult, but a bimanual examination of the pelvis will often enable a mass to be felt, and the sigmoidoscope gives useful information in some cases. A barium enema, if properly done, is of the utmost value, but only the very best x rays are of any use.

To obtain proper photographs certain things are essential. The photograph must be taken instantaneously. The enema should be made up with a thin medium, such as buttermilk. The exposure should be made some twelve hours after the enema has been evacuated.

There is a tendency for one or more of the diverticula to perforate as a result of sloughing of a concentration through the thin wall of the diverticulum, from gangrene of the diverticulum, or from the formation of a local abscess, which subsequently bursts into the peritoneal cavity or some other viscus. The latter is the most usual. Perforation into the bladder is not uncommon. An intense cystitis results with the passage of flatus and feces per urethram. Perforation, with the formation of local abscesses in the pelvis and one or more openings on the abdominal wall, is not uncommon. These abscesses are nearly always multiple, and proper drainage cannot be readily established.

The greatest interest attaches to those cases in which there is tumor formation from the deposit of dense fibrous tissue around the inflamed diverticula. Such tumors often reach a considerable size, and are almost invariably fixed and adherent to other structures. These cases are frequently confused with malignant disease. Evidence of inflammation and the presence of diverticula in other parts of the colon will help in the diagnosis, but such evidence is not always

present. Two distinct types of tumor may be recognized pathologically. In the more usual type, on laying open the tumor there are several large diverticula containing concretions surrounded by an irregular mass of very hard fibrous tissue. In the other type, the tumor consists of a dense mass of cartilaginous tissue of a pale gray color, through which can be traced numerous very narrow channels representing diverticula. These tumors are so hard as to be frequently mistaken for neoplasms. They are always adherent to other structures, and are generally situated at, or near, the middle of the sigmoid flexure.

The surgical treatment of diverticulitis presents many serious difficulties. The indications for surgical interference are as follows: 1, Persistent attacks of pain and tenderness in spite of careful medical treatment, the latter being directed to keeping the bowel contents liquid, and general means to improve the patient's resistance, rest, dieting, etc.; 2, attacks of threatened obstruction of the colon; 3, the presence of a palpable tumor in the colon; 4, evidence of threatened perforation into the bladder (attacks of pain in the left iliac fossa accompanied by frequent and painful micturition; 5, evidence of perforation with abscess formation or peritonitis.

Interference with the diseased bowel may easily set up grave sepsis or result in a fecal fistula, and great care and judgment is necessary. Colostomy well away from the seat of the trouble is the safest procedure and should not be dangerous if the diseased bowel is not too thoroughly explored, or not explored at all. Resection with end to end anastomosis and temporary cecostomy is the ideal treatment. As an alternative, wrapping the diseased bowel in omentum after freeing adhesions will give good results. When serious complications, such as local abscess, perforation into the bladder, or general peritonitis have already occurred colostomy is the only justifiable procedure.

The Etiology of Diverticula of the Intestine.—R. Davies-Colley (*British Medical Journal,* February 13, 1926) mentions three possible explanations, each of which he thinks is reasonable in that a parallel can be found for it in pathological processes occurring elsewhere in the body. They are as follows:

1. The subperitoneal fat weakens the intestinal wall by inducing a simple atrophy of the muscle from pressure.
2. The fat invades and separates the muscle fibers and so produces weak spots. In this case the natural line of invasion would be along the vessels which penetrate the muscular coat, so that these would be the most likely points for a hernia to occur.
3. The fat becomes infected, probably by the intestinal contents, and the muscle in contact with it is weakened by an inflammatory process.

Furthermore, in the light of x ray evidence, there would seem to be good grounds for believing that this last alternative is the true explanation of most of the diverticula occurring in the colon, though some in the colon and perhaps most of those in the small intestine, where infection of the fat is less likely to happen, may be ascribed to one or other of the noninflammatory causes suggested.

RADIOTHERAPY

Diathermy in Abdominal Operations.—G. W. Crile (*Surgery, Gynecology and Obstetrics,* Vol. XLII, No. 2) says that it must be borne in mind that on account of the enormous spread of the capillaries, veins, and arteries very near the surface of the viscera, in an abdominal operation the blood in the whole splanchnic area almost immediately assumes the temperature of the air to which it is exposed. Thus the application of a diathermy current in certain bad risk cases is advocated. One pole of the diathermy apparatus is placed upon the lower chest on one side and the other brought opposite the dome of the liver, so that the current passes through the upper abdominal organs including the liver. And since this current is applied continuously during the operation the temperature of the liver and of the abdominal viscera in the track of the electric current is maintained at or above the normal regardless of the exposure of the intestines. The electrodes can be put in place and the diathermy current established before the abdominal incision is made and neither the surgeon nor the patient need be aware that such a current is passing.

The higher incidence of pneumonia after abdominal operations than after operations of an equal magnitude on other portions of the body is well recognized. In view of this fact, and in view of the facts which we have cited one might well question whether this is not the result of the cooling of the blood in the important organs within the chest plus the general depressed function of the organism as a whole as the result of the cooling of the liver. We are therefore now noting whether or not the maintenance of a constant temperature in the liver and other abdominal viscera by the use of diathermy is lessening the incidence of postoperative pneumonia.

We are also using repeated doses of diathermy after operations in feeble and aged patients, and after especially wide and prolonged exposure of the upper abdomen, delivering the dose through the bases of the lungs, as this is the area where postoperative pneumonia is initiated. In addition to the advantage of heat, the increased temperature must induce a more active circulation in this area and thus increase the defense against infection.

Comparable to the effect of the direct application of heat by the passage of an electric current through the resistant tissues is the application of radiant heat energy by means of the Alpine or quartz mercury lamp. Just as this has been found effective in cases of lowered resistance, of tuberculosis, and so forth, we have found that it is equally effective when applied to anæmic and cachectic patients whose general resistance has been lowered by prolonged wasting diseases.

Heliotherapy.—John B. Hawes, 2d (*Boston Medical and Surgical Journal,* February 18, 1926), presents the following summary of his views on heliotherapy in tuberculosis.

1. Sunlight treatment is indicated in practically all cases of nonpulmonary or socalled surgical tuberculosis. It is not indicated in febrile cases of pulmonary disease or where there is other evidence that the condition is active.
2. Actual sunlight is better than artificial sunlight. If the latter is used by means of a lamp it should be as an adjunct to exposure to actual sunlight.
3. Heliotherapy should not be looked upon as the only means of treatment nor as the most important means of treatment but as an adjunct to rest, fresh air, proper nourishment and general hygiene.
4. Signs and symptoms of too much sunlight, whether artificial or real, are the same as a tuberculin reaction, probably from the same cause. They are increased temperature and pulse, general malaise, headache, debility, with sometimes renewed activity in the tuberculous focus.
5. Sunlight treatment, whenever possible, should be done under the supervision of the physician; in pulmonary cases, this is absolutely essential.
6. Sunlight treatment, in some form or another, can be carried on in the patient's home and does not necessarily require sanatorium or hospital equipment.
7. Sunlight treatment should be carried on methodically and if possible according to a definite schedule.

Fifteen Cases of Operable Carcinoma of the Breast Treated by Radium and X Rays.—J. H. Douglas Webster, J. P. Thierens and F. G. Nicholas (*Lancet,* February 27, 1926) are not in favor of radiation rather than operation in operable cases of breast cancer; radiation treatment is still too much in the experimental stage in its application to malignant disease, and its results are still too little known for this attitude to be adopted. At the same time radiation, which has sometimes led to the complete disappearance of inoperable growths and recurrences, should give very good results in operable cases, and radiologists therefore ought to study and discuss the problems of the treatment of operable breast cancer, for they never know when an operable case may be referred to them for some special reason.

In this series of cases every patient either refused operation, or else age, chronic bronchitis, heart disease, or glycosuria made operation inadvisable. The interim results suggest that such patients should be more freely offered the alternative of radiation treatment than they are at present; at least they should not be told that there is no alternative to operation. Eight cases were treated with x rays, two with combined radium insertion and x rays, and five with radium surface applications.

All of the five patients treated with radium did well locally, within the limits of the time that they were under observation. In each case there were supplementary medium voltage x ray applications to the epigastrium, lateral chest,

chest wall and axilla, supraclavicular triangles, opposite axilla and breast.

Summarizing the total fifteen cases there were two deaths, one due to an intercurrent disease, and one of the disease over two years after treatment was discontinued; in one case there was an abdominal metastasis. Of three new cases, one patient showed no sign of disease. One is having treatment for a radium dermatilis, the disease appearing arrested. The remaining eight have been in good general and local condition for some time.

Comparing the radium with the deep x ray cases, there is no notable difference so far in the results. The quantity of radium necessary for the thorough treatment of breast cases is so large that only a few cases can be treated with radium at present.

In conclusion one point should be referred to. This is the diagnosis, in cases where there is no histological confirmation. It has been shown that a positive expert surgical diagnosis of breast cancer is correct in about ninety-four per cent. of cases. On this proportion one (or at most two) of this series may not have malignant disease. But practically every case showed at one time or another, in addition to characteristic signs in the primary growth, axillary or supraclavicular gland enlargement or skin nodules. And in this series no patients with mastitis and possibly very early carcinoma were included; several cases of this nature have been treated so far with success.

Radiotherapy in the Treatment of Rodent Ulcer (Basal Cell Epithelioma).—F. Hernaman-Johnson (*Lancet,* February 20, 1926), believes that radiotherapy is the treatment of election for "virgin" rodents. In the case of a recurrence, rays of a different wave length from those originally used should be employed. If improvement is not manifest within a month some method of resensitizing the tissues, as by curettage or ionization, should be resorted to, after which radiation may again be given a trial. If these methods are not producing definite and continuous improvement at the end of two months the diathermic cautery should be employed. This method owes its success not merely to destruction of cancer cells, but to the sharp reaction produced in the surrounding tissues. If all recurrences are dealt with promptly there should be no need for surgery in the ordinary sense of the term. When, however, the recurrence has already assumed large proportions, it may be necessary to invoke the aid of the plastic surgeon to make good what has been destroyed.

The Röntgen Treatment of Hypertrophy of the Prostate.—Charles Guilbert and Robert D. Gauillard (*Urologic and Cutaneous Review,* March, 1926), state that röntgenotherapy of the hypertrophied prostate exerts its effect in most cases directly upon the pathological tissue, and according to most authors the hypertrophy seems to be an adenofibroma, in which the fibrous tissue, which remains unaffected by the x rays, becomes prevalent only toward the last. There are, therefore, two types of enlarged prostate: the soft ones with a preponderance of glandular element, and the hard ones, fibrous and sclerotic. In the first class, the röntgen treatment is powerful; in the second class it is questionable; practically, either may show improvement.

During the second week after the exposures, there is sometimes a vesical or rectal reaction. After the third week, the clinical results are obvious; the urinary retention decreases progressively to a few cubic centimeters, even sometimes to zero. In cases of acute retention in which spasmodic and congestive causes play a large part, sedation comes quickly and the early results are very brilliant. In chronic retention, the results are slow, but they appear after six weeks.

The most favorable cases are those of soft prostates in which the adenoma predominates. The greater the amount of fibrous tissue in the growth, the less brilliant are the results of radiotherapy. However, they never are *nil.* There is no contraindication for the röntgen treatment. Special attention, however, should be given to the dosage when there is some degeneration of the neoplastic form to be feared, in which case high dosage is necessary. In plethoric patients, furthermore, often having hemorrhoids, one finds a smooth, soft prostate and one expects a quick and definite result. But such are disappointing cases: these plethoric patients have their hypertrophy reduced for a short time, but six months or a year later, it recurs and there are some vesical symptoms. It is necessary in these cases to employ anticongestives to reduce the portal system and also to lower the blood pressure.

Relapses were observed in seven out of forty-five cases. The authors observed no adhesions or sclerotic changes that interfere with any future surgical operation, nor any neoplastic degeneration following the röntgenotherapy.

Irradiation of the prostate is a very mild treatment without danger for the future. It should be instituted as early as possible, as a beginning hypertrophy is less sclerotic, more sensitive to the x rays, and because the vesical symptoms are transitory and curable. In the presence of infected bladders, vesical irrigations and vaccines are indicated.

EYE AND EAR

At What Time Should a Cataract Operation Be Done?—M. Sachs (*Wiener klinische Wochenschrift,* March 11, 1926) asserts that an operation for cataract is never urgent. Usually there is sufficient time to correct any existing complicating factors that tend to minimize the good result of the operation. Not only must absolute asepsis and antisepsis be strictly maintained in the operation, but the operative field should also be uncontaminated with bacteria before an operation is undertaken. The edges of the eyelids should be free from inflammation, the conjunctivæ pale without any secretion. Epiphora should be corrected by probing of the nasolachrymal duct. Dacryocystitis should be taken care of. Conditions like diabetes, catarrhal infections of the respiratory tract and hypertension should receive the proper preliminary attention.

Maturity of the cataract, in itself, is not essential for its removal, but rather one should be guided by the condition of the other eye. If the latter is good, it is well to wait till the cataract is ripe. Conservative treatment, except with diabetic cataract, has always failed up to the present time. As about ninety-five per cent. of the cataracts remain almost stationary for years, all of the reports regarding apparent cures from treatment must be viewed skeptically.

There can be no doubt that the typical diabetic cataract is favorably influenced by continued insulin treatment, especially in young persons. In case the cataract is situated axially, sight may often be considerably improved by mydriatics. Naturally, there must be no suspicion of a predisposition toward glaucoma, which might be provoked by the dilatation of the pupil. In such cases the author puts a few drops of a one per cent. homatropine solution into the eye in the morning and a 0.5 per cent. pilocarpine solution before retiring to avoid a rise of pressure.

An Investigation of the End Results of Sixty Cases of Radical Mastoid Operation with Special Reference to Hearing.—J. A. Keen (*Journal of Laryngology and Otology,* March, 1926) comes to these conclusions: 1. The hearing that remains is quite independent of any points in the history previous to the operation. Provided the bone conduction remains good, the ultimate hearing has no relation whatever to the length of time the otorrhea has existed. 2. Hearing tests carried out before operation do not allow one to draw any conclusions as to the amount of hearing which will remain after operation, but are unreliable because the conditions in the middle ear are subject to constant changes. 3. The findings at the time of operation have no connection with the final hearing result, except that when cholesteatoma are found the hearing tends to be bad. 4. The type of operation cavity most favorable to hearing is the large, or moderately large, dry cavity lined by a thin epithelium. When the lining is firm and like skin, the hearing may be comparatively good. The hearing is poorest when the lining of the cavity is of the mucous membrane type with slight moisture. 5. Two hearing tests a year apart showed the hearing to be better in one third of the cases at the end of a year, to be worse in two thirds.

Anatomically Irregular Sphenoidal Sinusitis With Optic Neuritis, Localized by the Suction Syringe.— Patrick Watson-Williams (*Lancet,* October 24, 1925) states that the investigation of the sinuses in patients suffering from optic nerve defects, suspected to be of nasal origin, sometimes present special difficulties, owing, on the one hand, to the absence of any visible purulent discharge, and on the other to the irregular anatomical conformation of the sphenoidal sinuses and the ethmoid cells.

The sphenoidal sinuses show variations. Thus, one sphenoidal sinus may be large and overdeveloped at the expense of the other, so that the large sinus extends far

beyond the midline and consequently the small ill developed sinus may be, so to speak, packed away into a corner difficult of access. Again, the posterior ethmoidal cell may be unusually large and overdeveloped at the expense of the corresponding sphenoidal sinus, which may be so encroached on that the large ethmoidal cell occupies more or less the usual site of a sphenoidal sinus, or it may lie above the sphenoidal sinus, much as a first floor lies above the ground floor. While these anatomical variations are of no moment in health, it is quite another matter when the sinuses become infected and the focal infection causes partial or complete loss of vision, or, may be, is the primary and essential cause of rheumatoid arthritis, neuritis, neurasthenia, unsoundness of mind, and so forth, any or all of which do occur. If there is plentiful purulent discharge the indications for opening and draining the involved sinuses are sufficiently plain, but unfortunately such cases are less frequently associated with the complications mentioned than are the cases where the discharge is slight, macroscopically nonpurulent, and often unnoticed until inquired into. It is therefore important to detect and to localize precisely the source of any infective focus and, when confronted with anatomical irregularities in these, relatively small deep-seated sinuses, to avoid overlooking the focus, an error which may cost the patient his sight or worse.

The author obtains valuable information as to the size and infection of sphenoidal sinuses with the use of the suction syringe and cannulas. In a case reported, it was found that the left sphenoid extending well across the midline was entered as readily through the right as through the left nasal passage. Suspecting, therefore, that the right sphenoid was probably small and ill developed and had been missed, another cannula was entered, directed well outward, and the real right sphenoid was thus entered and explored, and yielded pure streptococcus on culture and film. The test applied was as follows. Two cannulas were inserted, one through the right nasal passage, the other through the left, so that both had entered what was presumed to be the large left sphenoidal sinus. Then, on attaching a syringe to one cannula and syringing down sterile water, it escaped out through the cannula in the other side. Again two cannulas were inserted both through the right nasal passage, one into the left sphenoid, the other directed outwards to enter the right sphenoid sinus, and on syringing water down the one it did not come up and escape by the other, showing that the two cannulas passed in through the right nose were in different cavities.

The practical point is that one thereby gains precise information as to the actual source of the extracted sinus contents and the bacteriological investigation tells whether it is or is not infected.

Ocular Pain.—A Freeland Fergus (*British Medical Journal,* September 19, 1925) asserts that, roughly speaking, pain in ophthalmic practice depends on two main factors: 1, uncorrected errors of refraction, of accommodation, or of muscular balance; 2, septic infection. In glaucoma, the relief depends upon operative procedure, although miotics relieve temporarily. The author prefers pilocarpine.

Errors of refraction must be accurately corrected as soon as possible. Relief from ophthalmic pain due to poor accommodation will follow the restoration of muscular balance.

The cause of a very large amount of ocular pain is briefly included in the word "sepsis." Iritis and cyclitis are always septic in origin. When a corneal ulcer or operation wound becomes painful it invariably means that sepsis has supervened. The cause of the sepsis should be removed by finding the nidus of infection and dealing with it. It is also important to identify the germ that is causing the mischief.

Clinically, inflammatory processes may be divided into two groups: those of mechanical origin, which are not self-sustaining and do not tend to extend beyond the original locus, and the bacterial, which continue the supply of the irritant and usually have the power of spreading. In an ordinary wound, the pain eventually wears off, but in septic conditions, the reverse is generally the case. Prolapsus of the iris, intraocular hemorrhage, and perhaps some other accidents, may cause pain; but pain following an ophthalmic operation after the lapse of some hours is almost invariably septic in origin. The infection may come from one of two sources: 1, defective technic; 2, disease, as iritis. The source is often in the blood, as in iritis due to syphilis or a specific urethral discharge, pyorrhea alveolaris, and sometimes affections of the intestinal tract. Chronic forms of iritis and cyclitis are often definitely known to be associated with tuberculosis. Most idiopathic, chronic or subacute inflammations of the uvea are due to either syphilis or tuberculosis. Atropine should, if tolerated, always be used in iritis, even when the tension is high. The cause of the pain must always be sought and corrected.

Ordinary corneal ulcers, seen in their early stages, should not be treated with cocaine; atropine is almost equally injurious. On no account should an eye with a corneal ulcer be bandaged, as it dams back the secretions. Drainage must be instituted, and the best method is the moderate use of a miotic, say a few drops of a 1 per cent. solution of pilocarpin put into the conjunctival, say once or at most twice daily. The eye should be douched at least three times daily with sterilized normal saline, and may be protected from excessive light by suitable glasses. This form of treatment prevents the development of a leucoma and hypopyon. Iritis need never be feared with this treatment.

The Optic Canal in Optic Atrophy.—Leon E. White (*Boston Medical and Surgical Journal,* October 22, 1925) has shown that excessive pneumatization of the sinuses adjacent to the canals produced narrowing and distortion. In a series of radiographs it was found that patients with optic nerve disturbances had abnormally small canals. By analyzing thirty-six cases of optic nerve involvement it was found that in the smaller canals the vision in fifty per cent. was permanently impaired, while in patients with larger canals the percentage was much less.

Sixty-seven cases of optic atrophy were studied. These were divided into five groups according to the size of the optic canal. Nasal infection was responsible for atrophy in twelve out of one hundred and twenty-four canals, or ten per cent. This occurred in the small canals,—nine in Group I and three in Group II. The other causes were as follows:

In twenty-four canals the atrophy followed brain tumors or pituitary disease.

In eighteen canals the atrophy was of luetic origin.

In eighteen canals the atrophy was congenital.

In fourteen canals the atrophy followed from diseased teeth.

In eight canals the atrophy followed retinitic pigmentosa.

In six canals the atrophy was from oxycephaly.

In four canals the atrophy was secondary to tonsillar infection.

In four canals the atrophy was from spinal meningitis.

In four canals the atrophy was from infantile paralysis.

In four canals the atrophy was from multiple sclerosis.

In two canals the atrophy followed cerebral hemorrhage.

In two canals the atrophy was unclassified.

Increased intracranial pressure seemed to be responsible for the abnormally large optic canals as intracranial lesions were found in all. Atrophy of the optic nerve in infancy was not responsible for the very small canals.

While it is possible to surgically enlarge the optic canal, cases are rarely seen at the stage when it would be beneficial.

The Operations for Glaucoma.—Samuel A. Durr (*American Journal of Ophthalmology,* March, 1926) sums up the matter in the statement that no one operation can be used in all cases. Iridectomy is the operation of choice in acute glaucoma, with preliminary posterior sclerotomy, or adrenalin, if needed. Trephining or iridotasis is permissible. The Elliot trephine should be used in chronic noncongestive glaucoma, especially with contracted fields. Iridotasis may be done. Cyclodialysis may be tried first, reserving the trephine for resistant cases. Iridectomy should be performed in glaucoma due to swelling of the lens. Buphthalmos is best combatted by trephining, or repeated posterior sclerotomies. Cyclodialysis should be used in glaucoma due to disease of the retinal vessels, and it may be done in patients who have chronic conjunctivitis. Adrenalin is valuable in ophthalmoscopic examination, as a therapeutic agent, and as an aid to operation.

Ocular Findings in Addison's Disease.—Albert L. Brown (*American Journal of Ophthalmology,* June, 1926) observed an advanced case of Addison's disease in which the patient presented bronzing of the lids with a darker line above the ciliary border of each upper lid. The pupils were dilated, while the fundus showed pigmentation around each macula and disc, with a zone of similar pigment deposits joining the two regions.

NEW YORK, WEDNESDAY, SEPTEMBER 1, 1926

Medicolegal Notes.

PRODUCTION BY INSURER OF RESULTS OF AUTOPSY ANALYSIS

In an action on an accident insurance policy where the defense was that death was by suicide, an order under Iowa Code 1897, §4654, required the insurer to produce papers, findings, and records of the laboratory analysis of the organs of the deceased's body removed during the autopsy. In a certiorari proceeding to test the legality of the order, the Iowa Supreme Court, Travelers' Ins. Co. v. Jackson, 206 N. W. 98, modified the order so as to require the insurer to furnish a copy of the direct results of the analysis, but not private correspondence or memoranda or expressions of opinion as between the insurer and its physicians.

DILATATION OF HEART FROM CRANKING AUTOMOBILE HELD NOT ACCIDENT

The Circuit Court of Appeals, Fifth Circuit, holds, Carswell v. Railway Mail Assn., 8 F. (2d) 612, that death due to dilatation of the heart, caused by cranking or attempting to crank an automobile two days before the death, was not the result of "external, violent and accidental means" within the meaning of an insurance policy. The court said that "where one voluntarily undergoes physical exertion, and nothing unexpected or unintended happens while he is doing so, the fact that such exertion unintentionally causes injury does not make the means whereby such injury is caused, namely, the voluntary exertion, accidental," and there was no evidence to support a finding that anything unexpected or involuntary happened while the insured was trying to start the car.

UNJUSTIFIABLE FRIGHT NOT REASONABLE GROUND FOR REFUSAL TO SUBMIT TO OPERATION

The New York Appellate Division holds, Palloni v. Brooklyn-Manhattan Transit Corp., 214 N. Y. L. 430, that compensation should be denied a claimant under the Workmen's Compensation Act if he unreasonably refuses to submit to an operation.

In this case the claimant sustained an injury which produced a right inguinal hernia and aggravated a preexisting condition on the left side which was predisposed to a scrotal hernia. Three physicians recommended an operation, to which the claimant refused to submit, alleging fear of the consequences. The court, reversing an award, said: "The question of reasonableness may be one of fact, and if so found, is binding on this court, but in this case there is no dispute of fact. There is a single question, Was unjustifiable fright a reasonable ground for refusal to submit to an operation which had been recommended by physicians representing the claimant, the employer, and the Industrial Board, and consequently presumed to be for the best interests of the claimant, especially where there is no proof that such operation is fatal or even dangerous? As a matter of law, it must be held that such fright alone was not a reasonable ground for refusal." This appears to be the first reported case in the New York courts on the subject, but the court cited cases showing that the rule followed is well established in other jurisdictions.

CHIROPRACTORS REQUIRED TO PASS MEDICAL EXAMINATION IN MICHIGAN

In a prosecution of a chiropractor for violation of the Michigan Medical Practice Act (Gen. Laws 1915, Sec. 6724 et seq.) by practising medicine without a certificate of registration or license, the defendant contended that the act, requiring registration and fixing qualifications of all persons practicing medicine, is unconstitutional, unreasonable, arbitrary and violates the federal Fourteenth Amendment. Counsel for defendant insisted the statute operates to prohibit chiropractors from obtaining a license because it requires them to pass an examination before a medical board in subjects which no school of chiropractic teaches, and which are not used by them in the practice of their profession. The Michigan Supreme Court, People v. Lewis, 233 Mich. 240, 206 N. W. 553, affirming conviction, said: "We take it that defendant desired to practise a system of treatment of human ailments or diseases without the use of drugs. If so, is it unreasonable to require him to pass an examination before a board of qualified experts in the subjects of anatomy, histology, embryology, physiology, chemistry, bacteriology, pathology, diagnosis, hygiene and public health?

"It is within legislative power to require persons practising treatment of human ailments or diseases without the use of drugs to possess knowledge of organic structure, intimate structure of tissues, embryonic evolution, functions of the body, molecular and atomic structure of bodies, microorganisms, science of diseases, morbid processes observable in various diseases of organs, recognition of disease by its symptoms, science of health, and efforts made and measures and precautions deemed advisable for the promotion and protection of public health. This power has been exercised, and the regulation provided must stand, unless violative of rights guaranteed by the state or the federal Constitution. We find no limitation upon the subject in the state Constitution. We can conceive of no deprivation of the equal protection of the law in requiring drugless healers to understand the subjects mentioned. The fact defendant has not received instruction in some of these subjects offers no objection to the validity of the law. We decline to indict the medical profession of design to annihilate the system of chiropractic adjustment and the Legislature of supinely surrendering the lawmaking power in aid thereof. It may be that no chiropractic school teaches all the subjects mentioned, and chiropractors feel that a knowledge thereof is unnecessary and unused in their school of practice, but this affords no reason for requiring the Legislature, in recognition thereof, to enact no law not in conformity therewith."

NECESSITY FOR FORCIBLE DELIVERY HELD FOR JURY—EXCESSIVE DAMAGES

In an action for alleged malpractice in a confinement case to recover damages for the benefit of plaintiff's child, whose leg was fractured and arm paralyzed by the manual force exerted by the defendant, the attending physician, in the alleged negligent and premature delivery thereof, the Minnesota Supreme Court held, Korman v. Hagen, 206 N. W. 650, that there was testimony contradicting the findings of the defendant as to the necessity of making a forcible delivery, which carried the issue of the negligence to the jury.

The defendant was dismissed within 48 hours of the birth of the child, and other doctors called to take charge of the case. The trial court charged the jury that the defendant could not be held responsible for the augmented damages caused by the subsequent negligent treatment of the child's injuries. Under the evidence and the law thus given, which the jury were bound to follow, it was held that no large sum could be assessed against the defendant for the arm injury, for it appeared that, although the doctor who superseded the defendant discovered that injury in time likely to affect a cure by simple treatment, none was given. The evidence not justifying a large sum for the arm injury, the verdict was held so excessive as to indicate passion and prejudice on the part of the jury, and a new trial was granted unless plaintiff should consent to a reduction to $4,000.

Gastrointestinal Diverticula*

WILLIAM SEAMAN BAINBRIDGE, Sc.D., M.D., C.M.
New York

The comprehensive study of diverticula of the intestines is a comparatively recent phase of medicine. Until twenty-five years ago, acquired diverticulations of the colon were considered pathological rarities, though it is true that Sir Charles Ball wrote a paper on the subject in the early eighties and various other writers called attention to these abnormalities from time to time. However, the first really extensive work concerning diverticula in this portion of the canal was published by Telling (W. H.) in 1908. Up to this time, few text books of surgery had given much space to these diverticula.

In a recent paper, Dr. W. W. Babcock said: "It is curious that the profession has been so slow to appreciate the pathological condition of diverticulitis. Most of us as students heard or read nothing of diverticulitis. The *American Textbook of Surgery,* which we studied, was edited by two well known Philadelphia surgeons; and in this book no reference was made to diverticulitis and yet both of these authors later developed the condition. Both were operated upon with intestinal resection and both recovered from the operation. One, some years later, died with secondary malignant involvement of the spine; the second had a nonmalignant type and fortunately is still living. These were among the earlier cases reported by Dr. Mayo. Our largest encyclopedia of medicine and surgery had no reference to this condition. The editor, also a noted Philadelphia teacher and author, had diverticula and was operated upon."

From the quotation cited above, one may deduct that this condition of the gastrointestinal tract is far more common than is generally supposed. I feel that, to date, the importance of these diverticulations has not been altogether appreciated by the medical profession. Diverticula of the intestinal tract have not had the attention they merit!

Diverticula are divided into two classes—congenital and acquired. The cause of these intestinal pouches is still, more or less, a matter of speculation. Some writers hold to the embryonic or congenital theory of origin. G. S. Huntington, Professor Keith of the Royal College of Surgeons, London, and Professor J. R. Eastman, in the dissection of numbers of fetuses, found many prenatal structures in the abdomen. These, doubtless, persist in the adult, thus accounting, in many instances, at least, for certain types of intestinal diverticula. Keith states that these diverticula are outgrowths of intestinal epithelium which are formed during the third month of life and which perforate the muscular (intestinal) coat. They usually disappear, but, occasionally, they, with masses of pancreatic tissue attached to them, later, are found and may be the original source of a certain proportion of intestinal diverticula. The most common of the structures which remain in the adult intestine is Meckel's diverticulum, which was described by the anatomist, Meckel, in 1805. It occurs in two per cent. of subjects and commonly forms a finger-like sac on the free border of the ileum, from two to four feet above the ileocecal orifice. This diverticulum varies in length and shape; its blind end is frequently bulbous and the site of secondary diverticula. There have been one or two cases reported in which a Meckel's diverticulum has been found in several children of the same family (Warren), and Kelly reports that such diverticula are often associated with other abnormalities—harelip; spina bifida; atresia of the anus, and double or triple monsters.

A very unusual pathology of (Meckel's) diverticula has recently been cited by Stulz and Woringer of Strasbourg, France, who have accumulated twelve cases of peptic ulcer of diverticula in children. These writers state "that the first and at the same time the most constant sign of this condition is abundant intestinal hemorrhage. The hemorrhage may last for days or even weeks. If the child keeps alive and if there is no perforation, the hemorrhage stops after a lapse of time, but only to start afresh after some weeks or months. This tendency to repetition constitutes, together with the abundance and red color of the blood emitted, the main characteristic in peptic ulcer of a diverticulum." All of the ulcers (cited by these writers) were subjected to histological examination and "were found to have developed on the margin mucosa area." This ulcer of the diverticulum has nothing to do with "diverticulitis." "The latter stands in the same relation to the diverticulum as appendicitis to the cecal appendix."

In summing up the treatment of congenital diverticula with peptic ulceration, Stulz and Woringer state "that the only logical measure is surgical removal."

In acquired diverticula, three pronounced types stand out; the inflammatory; the traumatic, and the evolutionary. Of these, the inflammatory is, perhaps, the most widely recognized. This type is often the result of peritoneal reaction within the intestine, an infection such as that of the typhoid bacillus, or it may result from some inflamed organ in the immediate vicinity. Chronic mild infections of the peritoneal covering of the cecum and appendix, transmitted through the intestinal wall, are considered by some as responsible for these diverticulations.

Many writers, including Moynihan, call attention to the association of duodenal diverticula and ulcers; Dickey (S. B.) thinks "that in such cases the diverticula are probably out pocketings due to perforation of an ulcer; cicatrization, or to some other condition dependent on inflammatory change."

The traumatic theory of origin is closely allied to that of the inflammatory since, though the trauma may occur from without or within the gut, the resulting diverticulation usually takes place at a site in the intestine weakened by chronic inflammation or by an infective process.

Of the various hypotheses offered to explain acquired intestinal diverticula, perhaps the one which accounts for the greatest number of these sacculations is the mechanical or evolutionary theory. Sir Arbuthnot Lane's interpretation of the evolutionary accessory ligaments and bands, acquired by man to counteract the tendency to enteroptosis, incident to the disturbed mechanical relations of the bowel, consequent upon the assumption by man of the upright position, needs no elaboration here. It is too well known. The theory may be applied to intestinal diverticula in that, if continued pressure or stress and strain will change the bony structures of the body, it certainly will produce changes in the soft tissues—and there is no reason why the viscera of the abdominal cavity should prove an exception to this principle. Personally, I believe that a large proportion of intestinal diverticula have their origin in the mechanical factors of constipation, persistent enteroptosis and continued excessive distention of the intestinal canal. The overloaded and distended bowel throws an abnormal strain upon a fixed point in the tract until, finally, the intestine succumbs to the continued pressure (possibly at a site already weakened congenitally or by an old inflammatory process), the mechanical relations of the bowel are impaired and an angulation or a diverticulation may result. Back pressure of this type frequently occurs at the cecum with resultant diverticulosis of the wall.

Since the introduction of the x ray, in the diagnosis of gastrointestinal conditions, it is apparent that acquired diverticula may be found anywhere in the alimentary canal. In many cases the diverticula are multiple. They are quite common in the large intestine. Of forty cases reported by Sudsuki, fifteen were in the sigmoid. Case (J. T.) reports that in 6,847 barium meal studies, he found duodenal diverticulosis in eighty-five cases, diverticulosis of the jejunum in four cases, and diverticulosis of the ileum in one case. In the same series, colonic diverticula were found in 138 cases. The Johns Hopkins Hospital statistics on 2,600 necropsies, record thirteen diverticula, other than Meckel's, in the small intestine and eighteen in the colon. Linsmayer found forty-five cases of duodenal sacculations in 1,367 necropsies.

Beer states "that diverticula of the sigmoid are peculiar in that they alone seem likely to undergo extensive pathological change." There are few statistics available to indicate how frequently carcinoma occurs at the site of a diverticulum. Lynch reports the coexistence of carcinoma and diverculitis in four out of twelve cases of intestinal diverticula. In 116 cases of intestinal diverticula seen at the Mayo Clinic, malignancy was found in fourteen.

At times a diverticulum may become enormous and contain fecal matter; perhaps also fecal concretions. I recently found and removed an enterolith the size of a hen's egg from a diverticulum of the jejunum. Diverticulations may evidence no symptoms whatever, or may become inflamed, cause suppuration and perforate. Da Costa suggests that a diverticulum of the intestines sometimes is the focus of a large fibrous area which may be mistaken for cancer. Wilson (L.) also has called attention to a low grade chronic infection of these sacculations causing a peridiverticulitis or extramucosal inflammation with formation of a mass simulating cancer.

As previously stated, diverticula of the intestines may remain healthy for years and then undergo pathological change. A condition which frequently develops in a diverticulum is a diverticulitis—chronic or acute. This inflammatory process may be limited to a single diverticulum in any portion of the intestinal canal or it may spread and inflame multiple diverticula. The inflammation may progress until an abscess forms. Occasionally the abscess will perforate into the intestines.

There is a wide difference of opinion, in the medical profession, concerning the treatment of intestinal diverticula—with or without accompanying diverticulitis. Case (J. T.) writes "that although in the majority of cases seen at necropsy there have been few indications that treatment was needed, this cannot be stated as generally applicable to diverticula of the duodenum discovered with röntgen rays. The later category of these patients frequently suffer from some more or less chronic digestive complaints, usually suggestive of right upper quadrant trouble, and there is always the possibility that there may exist some well defined connection between the diverticulum and the patients' symptoms. Dr. Case adds: "duodenal contents were found in a diverticulum on the seventh day after an opaque meal, in one of my cases. The evidence before us, therefore, strongly suggests that the diagnosis of a duodenal diverticulum may generally be considered as indicating a surgical operation." Peck (C. H.), on the other hand, wrote thus: "diverticula without symptoms are common and call for no treatment. Patients should be kept under careful observation if any danger of perforation or abscess formation is present. Perforation, with localized abscess, or peritonitis, of course, calls for prompt intervention; sometimes simple drainage is sufficient. Persistent chronic thickening of the mass, with subacute symptoms, demands exploration and often resection of the gut to exclude malignancy, or to remove a definitely thickened segment."

Where diverticulitis is present, and the patient a poor risk, surgically, Drueck prescribes palliative

treatment. He indicated, in such cases, a course of therapeutics which includes "keeping the feces soft or liquid (with laxatives and oils, never purgatives)" and he prescribes "belladonna and morphine; liquid diet, and frequent high enemas—the patient to be kept under careful observation, meantime, for evidence of stenosis of the bowel, or peritonitis."

At this point I wish to digress for a moment, to emphasize the possible danger attached to the administration of high enemas in the treatment of intestinal diverticulitis. Such enemas must be given with the greatest care and with the minimum of pressure. A heavy stream of water suddenly directed against the weakened musculature may cause the wall of the intestine at the diverticulum to give, with resultant bulging of the gut and marked increase in the size of the diverticulum. Another factor associated with the rectal enema in intestinal diverticula is the injection of bismuth. Is it possible that some of the cases of large intestinal diverticula impossible to demonstrate by x ray and yet found, later, during operation may be explained on the basis of the applied force of the bismuth enema? Injection into the gut of heavy pressure from below, which thereby reverses peristaltic action, may cause a constriction of the entrance to the diverticulum which eliminates the sacculation from the field of x ray exposure. In these cases, opaque enemas may be less useful than the administration of bismuth by mouth. Better still, in all cases of suspected diverticula of the intestines, a full set of x ray plates should be made.

Roberts (D.) who agrees with Drueck that medical treatment of diverticula (of inflammatory type) will almost entirely relieve symptoms, in many instances, says that these types do better without laxatives which cause liquid stools; and suggests that weekly or biweekly doses of barium or bismuth, one ounce in emulsion or buttermilk, is exceedingly useful. He prescribes, where there is evidence of subacute catarrhal inflammation, injections of a solution of gelatin introduced into the sigmoid. For severe spasm of a particular part, or even of the entire colon, he says that the urea derivative, luminal, has immediate and absolute effect.

Moutier and Percher report a case of gastric ulcer of the lesser curvature, with a large diverticulum, in a man aged fifty-two. A dose of ten grams of bismuth was given, three times a day, with milk and starchy food. Alkalines were allowed only to relieve pain. In two months the pains subsided completely; a month later (under twenty grams daily) there were no signs of the diverticulum on röntgen ray examination. The bismuth was continued (ten grams a day) for two months longer, and the patient was apparently cured.

I believe that there is a considerable percentage of small, multiple diverticula which seem to cause no symptoms, or very mild symptoms, and which are benefited by medical treatment. However, there must be many more cases than we know today, where the symptoms are legion, but remain unrecognized, or are attributed to other pathology.

While the etiology of diverticula may remain somewhat obscure, the abnormal conditions which arise in the intestines as the result of these sacculations are obvious. Where these intestinal diverticulations are present in the large bowel, it is evident that they must fill with feces, which in such areas of local stagnation often become putrefactive. Distention of the gut, as the result of the backward pressure of the fecal content, occurs (particularly in the cecum) and various degrees of obstruction follow. As a result of this static condition, varying grades of ulceration and inflammation may occur. There is likely to be lowering of the vitality of the individual by autointoxication, as well as the direct effect of the autointoxication upon the structures and tissues of the body. In an earlier paper, reference was made to the close relationship between toxemia originating in the intestinal tract and many, apparently, remote symptoms in the patient. Enlarged or atrophic thyroid glands, "lumpy breasts"; certain types of psychoses; affections of the heart muscle; and chronic abnormal conditions of the digestive organs may be eliminated, in many instances, by the correction of a static condition of the intestinal canal. It is because I firmly believe that a great number of these pathological factors are due to inadequate drainage of the alimentary canal that I wish to emphasize the importance of prompt surgical correction of symptomatic intestinal diverticula which are not relieved by a fair trial of medical measures. In seeking foci of infection, the intestinal tract, as a whole, has not had the attention it merits.

The following cases are cited to illustrate that the causative factor in many and varied abnormal mental and physical conditions is retarded drainage of the intestinal canal, due ofttimes to congenital or acquired bands, kinks, sacculations and diverticulations in the tract. The restoration of the patient to normal by the elimination of these areas of stagnation, is proof of the soundness of the theory.

Case I.—E. A.; female; eleven years of age. This patient came under my care in June, 1916, sent by Dr. Graeme Hammond. The birth and early childhood were normal except for chronic constipation which was present even during babyhood, when it was necessary to give the child an enema almost daily. X ray of the skull showed no abnormality. The family history was negative.

In September, 1915, at ten years of age, the patient had attacks of what was apparently petit mal—as many as twenty a day. She was placed in a hospital where she remained for four months taking a rest cure; on a fruit and vegetable diet for eleven weeks and, later, on a milk diet for five weeks. Dr. Hammond barred out essential epilepsy.

On clinical examination I found distinct tenderness over the head of the colon and the appendix. The large intestine was prolapsed; the cecum was much distended and lay in the true pelvis. X ray of the intestinal tract showed "a delay in the passage of the intestinal content through the terminal ileum, the transverse colon and sigmoid. The appendix retained barium for several days. The colon plates, twenty-two, forty-seven and seventy hours after the injection of the solution, showed that a large amount of the barium was retained in the colon, and dilated the cecum and ascending colon."

Operation was performed June, 1916. The gallbladder was distended and attached to the first portion of the duodenum by a tight band which continued down over to the transverse colon, near its hepatic flexure, which was prolapsed. The stomach was

dilated to an unusual degree for so young a child, the greater curvature extended almost to the bladder. A band, about three inches broad, ran from within an inch of the tip of the gallbladder to the vessels of the gastrohepatic omentum. There was a duodenal kink of marked degree. Just above the cecum, the

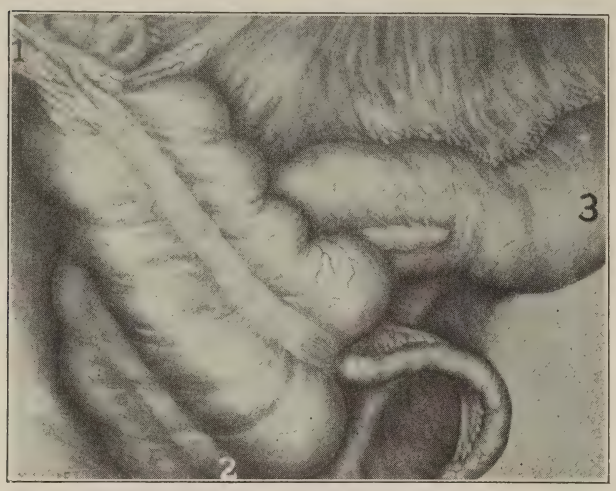

FIG. 7.—Case IX. E. B. 1, band of constriction with malignant disease at site of former irritation; 2, large dilated cecum; 3, distended ileum.

ascending colon was bound down tightly; the hepatic flexure was fused with the ascending colon and the sigmoid was very redundant. There was a large diverticulum of the cecum. The bands were severed; the diverticulum turned in; the cecum was plicated, and the cecum and ascending colon were elevated, rotated outward and anchored to the posterolateral shelf.

Following the operation the nerve condition rapidly improved. The seizures of petit mal were reduced to a minimum and, except for a slight attack at long intervals (and these usually followed a protracted excitement or fatigue), finally disappeared. The patient has remained in excellent health and has made a brilliant record as a student in high school and in her first year of college. She enjoys all the pursuits of the perfectly healthy girl and, on examination in August, 1925, I found her normal in every respect, while a letter received May, 1926, states "that she continues in fine health."[1]

CASE II.—L. B.; female; twenty-four years of age; single. This patient consulted me February 26, 1917. She had a large goitre and enlargement of the heart with systolic murmur at the apex and base. She was very nervous, and complained of almost constant diarrhea and gastrointestinal distress. There was enteroptosis with distinct ileal tenderness. X ray examination showed a kinked terminal ileum and the cecum in the pelvis. The appendix also was kinked and the cecum was markedly diverticulated.

The patient was suffering so much from pressure of the goitre that partial thyroidectomy was performed and the right half of the gland and isthmus removed. However, the abdominal symptoms still caused distress and February 8, 1918, laparotomy was performed; the appendix removed; the ascending colon anchored, and the diverticulated cecum plicated and anchored in normal position. The remaining half of the goitre slowly decreased in size (to normal) after the abdominal operation.

The recovery was uneventful and in January, 1925, the patient reported that there had been no return of the goitre or the gastrointestinal symptoms.

CASE III.—M. B.; female; forty years of age; married; six children. A year before consulting me this patient had pain in the right lumbar region, the right lower quadrant, and soreness throughout the abdomen. She had attacks of nausea at intervals and occasionally vomited blood. On physical examination, distinct tenderness was found over the appendix and resistance over the gallbladder and the duodenum.

Laparotomy was performed April 24, 1917. A band ran across from the greater curvature of the stomach and edge of the omentum, tightly binding down the ascending colon and that portion of the transverse colon which had become coalesced with the ascending colon by intercolic bands, and obstructing the ascending colon. The cecum was badly diverticulated and filled with fecal matter. The last kink was accentuated. The appendix was removed; the bands were relieved, and the large gut was placed back in its normal position.

Convalescence was uneventful. Following operation, all gastrointestinal symptoms disappeared. Word received from the patient, March 3, 1926, said, in part, "that she was in splendid condition and had had no abdominal symptoms since the operation."

CASE IV.—W. B.; male; thirty-eight years of age; married. In 1913 this patient was operated upon for chronic disease of the appendix and intestinal bands and kinks. At the time of this first operative procedure, the condition of the patient was such that, although a partial colectomy seemed necessary, it was considered advisable to try conservative surgery. Following the first operation the patient improved and gained twenty pounds in weight, but he still continued to exhibit symptoms of toxemia (with headache, vomiting at times, and marked constipation). The x ray showed a diverticulum of the ileum, and sites of fecal accumulation in the cecum, ascending and transverse colons, and colectomy was decided upon.

Laparotomy was performed January 7, 1916. The mesocolon was carefully separated from its adhesions, ligated in sections up to and including the splenic flexure; the colon at this point was encircled proximally with a purse-string suture; its stump was crushed, ligated and separated by cautery. The stump was then inverted and secured in position by a double row of Lembert stitches. Raw surfaces were covered by a peritoneal flap. The two inch Meckel's diverticulum of the ileum, which was about twelve inches from the ileocecal valve, was removed. An ileocolostomy with the pelvic colon was done.

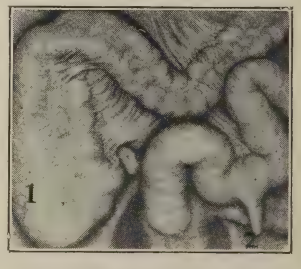

FIG. 8.—Case IV. W. B. 1, large reservoir of septic poison; 2, ileal diverticulum.

Following the operation all symptoms of toxemia disappeared. There were no longer any attacks of

[1]Preliminary report in Bainbridge, William Seaman, The Constitutional Effect of Prolonged Intestinal Toxemia (MEDICAL JOURNAL AND RECORD, October 21, 1925).

gastrointestinal distress or vomiting; the headaches and constipation were relieved. The patient's digestion improved greatly. In six months he gained seventy-five pounds.

Since 1916, at intervals, he has reported his continued good health, and on March 3, 1926, he stated "that he has had no recurrence of symptoms and that his cure is entirely complete."

Case V.—A. J.; male; fifty-three years of age; married. This patient consulted me because of severe attacks of constipation; retching each morning before breakfast, and vomiting immediately after each meal. His weight had decreased twenty pounds in six months.

Clinical examination showed a tense epigastrium; stomach and ascending colon dilated and medium tenderness over McBurney's point. After two months of medical treatment, with very little result, surgery was advised .

Laparotomy was performed December 19, 1920. On opening the abdomen there were found a band of adhesions across the duodenum and a tight band from the top of the gallbladder to the common duct and extending downward to the transverse colon, about four inches beyond the hepatic flexure. The cecum was dilated by a retrocecal diverticulum and twisted from without inward and downward. This caused an angulation of the middle of the ascending colon. The bands were cut transversely and sewed longitudinally. The cecum was plicated and fastened to the posteriolateral wall. The raw surfaces were all turned in.
